# NAME INDEX

- Abdel, Magid, A. M. : Respiration of Air by the Primitive Fish *Polyporus senegalensis*, 1096
- Abraham, R., Golberg, L., and Grasso, P. : Hepatic Response to Lysosomal Effects of Hypoxia, Neutral Red and Chloroquine, 194-6
- Aceves, Jorge, and Erlil, D. : Effects of Norepinephrine on Tissues of the Frog Heart Atrium poisoned by Tetrodotoxin, 1178
- Adair, J. D. : Vectorial Metabolism, 78
- Aded, P., Brown, D. M., Knudsen, E. T., Robinson, G. N., and Sutherland, R. : New Semi-synthetic Penicillin active against *Pseudomonas pyocyanea*, 25-30
- Accor, P., Anderson, E. L., DeCullo, C. J., Ferlauto, R. J., Hoover, J. R. E., Pagano, J. P., Ravin, L. R., Scheidy, S. P., Steadman, R. J., and Theodorides, V. J. : New Broad Spectrum Antihelmintic, Methyl S(6)-Butyl-2-benzimidazolecarbamate, 321
- Ada, G. L. : see under Parish, C. R.
- Adams, G. E., Michael, B. D., and Richards, J. T. : Three Stage Electron Transfer in Aqueous and Alcoholic Solutions, 1248-50
- Agustin, B. M., and Cressley, W. A. : Vinca Alkaloids and the Synthesis of RNA in Mouse Brain, 965
- Abearm, M. J., Lewis, C. W., Campbell, L. A., and Luce, J. K. : Nuclear Bleb Formation in Human Bone Marrow Cells during Cytosine Arabinoside Therapy, 196
- Ahmed Khan, Imtiaz, and Ataur Rahman, M. : Variation of Saccharoid Fraction in Diabetes Mellitus, 979
- Ahmed, S. J., and Taylor, H. P. W. : Crystal Structures of the Lamellar Calcium Aluminate Hydrates, 622
- Aidley, D. J. : Invertebrate Nervous Systems : their Significance for Mammalian Neurophysiology, review, 1525
- Anaworth, E. John : see under Haake, Gerald E.
- Anaworth, G. C. : Obituary of Dr S. P. Wiltshire, 221
- Ajmal, M., Hobbs, B. C., and Mulcahy, M. P. : Causes and Effects of Columnar-type Diseases in Fish, 141-4
- Alcock, C. B. : see under Kubaschewski, O.
- Aldaz, Luis : Surface Air Radioactivity and Ozone at Amundsen-Scott Station (90° S), Antarctica, 722
- Alderson, Thomas : Induction of Genetically Recombinant Chromosomes in the Absence of Induced Mutation, 1281-3
- Alderson, T., and Khan, A. H. : Caffeine-induced Mutagenesis in *Drosophila*, 1000
- Alford, T. C. : see under Hollinshead, A. C., 397, 399
- Alfrey, G. F. : Luminescence of Inorganic Solids, review, 677
- Allan, E. : see under Warburton, P. G.
- Allan, H. R., Neat, K. P., and Jones, J. K. : Mechanism of Radio Emission from Extensive Air Showers, 267
- Allen, Clifford : Mental Illness, review, 673
- Allen, C. P. : see under Kendall, J. W.
- Allen, J. B. : Pyroclastic Origin of Supposed Microfossils in the Roman Formation, Guyana, 1261
- Allen, R. C. : see under Tyndall, R. L.
- Allen, Shirley H. : see under Marston, Hedley R.
- Alley, C. O. : see under McCormick, P. D.
- Allison, A. C., Bertram, L. D., and Levey, R. H. : Increased Tumour Induction by Adenovirus Type 12 in Thymectomized Mice and Mice treated with Anti-lymphocyte Serum, 185-7
- Allison, A. C. : see under Strik, M. A.
- Almy, Rydis : see under Kelly, Sally
- Altmann, Stuart A. (edited by) : Social Communication among Primates, review by Y. Spencer-Booth, 699
- Altuzuler, Norman : see under Margolis, Richard U.
- Amies, F. A. : see under Robinson, P. A.
- Amin, A. H. : see under Subbiah, T. V.
- Amster, Adolph B., and Woolfolk, R. W. : Anomalies in Decontamination Initiation of Liquid Explosives, 1370
- Anders, P. : see under Hadorn, B.
- Anderson, B. W. : Book of Minerals, review, 443
- Anderson, E. C., Petersen, D. F., and Tobey, R. A. : Biochemical Balance and Synchronized Cell Cultures, 1083
- Anderson, E. L. : see under Actor, P.
- Anderson, E. S. : see under Duguid, J. P.
- Anderson, J. : see under Coulson, R.
- Anderson, John S., Brecher, M. S., Clark, B. F. C., and Marcker, K. A. : AGTP Requirement for Binding Initiator tRNA to Ribosomes, 490-2
- Anderson, Sydney, and Jones, J. K. (edited by) : Recent Mammals of the World : Synopses of Families, review by L. Harrison Matthews, 1314
- Ando, Ken J. : see under Mull, Jun., Arthur H.
- Andrade, O. : see under Bodlaender, K.
- Andrew, J. : see under Epstein, Samuel S.
- Andrew, B. H., Purton, C. R., and Terzian, Y. : An Upper Limit to Circularity Polarized Radiation from the Crab Nebula, 493
- Andrews, C. H. : Obituary of Dr A. W. Gledhill, 1107
- Andrews, Frank M. : see under Patz, Donald C.
- Anesey, Joan : see under Vels, Arthur
- Anisimov, V. : see under Phillips, D.
- Anker, P. : see under Stroum, M.
- Anscobabe, G. E. M., and von Wright, G. H. (edited by) : Zettai (L. Wittgenstein), review by P. I. G. Rawlins, 557
- Antonovych, Tatiana : see under Pabily, Akunysle
- Aoki, Masahiko : Optimization of Stochastic Systems : Topics in Discrete-Time Systems, review by A. P. Roberts, 328
- Apostolov, K., and Fishman, B. : Purification and Concentration of Influenza Virus by Auto-aggregation, 1287
- Apparao, M. V. K. : Upper Limit on the Abundance of Anti-protons in the Low Energy Galactic Cosmic Radiation, 727
- Applegarth, D. A., and Borzozan, G. : Artefact of Hydrolysis of Glucosamine Derivatives, 1382
- Arasimowicz, C. : Repression of DNA Synthesis in Mouse Liver Cells after Unilateral Nephrectomy, 756
- Arands, Tullio : High Concentrations of Haemoglobin A<sub>2</sub> in Malaria Patients, 1517
- Armitage, Angus : John Kepler, review by J. R. Ravetz, 1009
- Armstrong, Bruce W. : see under Blankenhorn, David H.
- Armstrong, H. L. : Unfair to Aristotle, Correspondence, 1212
- Arnold, P. W. : Soil Chemistry and Fertility, review, 560
- Arnstern, H. R. V. : The Cytology of the Protein Synthesis in an Animal Cell, review, 446
- Astrakan, Mira : see under Henriques, Olga B.
- Acanaslu, P. : see under Vilagines, R.
- Ataur Rahman, M. : see under Ahmed Khan, Imtiaz
- Atchison, Robert W. : see under Raposa, Norbert P.
- Atkinson, R. J. : see under Hingston, P. J.
- Atwater, Ilanil : see under Rojas, Eduardo
- Atwood, H. L. : Variation in Physiological Properties of Crustacean Motor Synapses, 57
- Auquere, J. P. : see under Nyns, E. J.
- Austin, George M. : see under Sato, Makoto
- Axelrod, Julius, et al. : Distribution of the Adrenaline-forming Enzyme in the Adrenal Gland of a Snake, *Xenodon merremii*, 879 ; see also under Snyder, Solomon H.
- Axon, Rolf : see under Ppnsch, Jerker
- Axon, H. J., and Kleche, R. : The Gopse Lake Meteorite and the Goose Lake Fragments, 379
- Aylward, Dr F. : Appointment as Professor of Food Science in the University of Reading, 221
- Ayres, Priscilla : see under Greaves, J. H.
- Bachelard, H. S. : Glucose-phosphorylating Enzyme with High Km in Human Brain, 959
- Bachl, C. : see under Pazio, M.
- Bechman, George, and Narici, L. : Functional Analysis, review by F. Smithies, 1523
- Beckett, Professor E. Maurice : Appointment to Chair of Community Health in the Medical School at the University of Nottingham, 1528
- Bedami, D. V., Joiner, J. C., and Jones G. A. : Microstructure of High Strength, High Modulus Carbon Fibres, 386
- Bedar, Richard G., Jarlov, N., Karlik, B., and Thorhaug, A. : Obituary of F. F. Kocay, 563
- Bagby, John P. : Radio Anomalies associated with an Ephemeral Satellite still in Orbit, 1050
- Bagnall, Dr R. W. : Appointment to Chair of Inorganic Chemistry at the University of Manchester, 680
- Bagnall, K. W., and Holah, D. G. : Actinide Chelates : Uranium (IV) *N,N*-Diethyldithiocarbamate, 623
- Bailey, D. K. : The Lovozero Alkali Massif, review, 106
- Bailey, J. Leggett : Techniques in Protein Chemistry : Second Edition, review by H. N. Rydon, 1105
- Bailey, Winston J. : Further Investigations into the Function of the "Mirror" in Tectigonioides (Orthoptera), 762
- Baillis, Ann : see under Thomsen, R. O.
- Balstner, Jun., K., and Veress, B. : Longitudinal Differentiation of the Small Intestine, 774
- Baker, Herman, Frank, O., Fengold, S., and Levey, C. M. : Vitamin Distribution in Human Plasma Proteins, 84
- Baker, I., Gale, N. H., and Simons, J. : Geochronology of the St Helena Volcanoes, 1451-6
- Baker, John R. : The Student's Microscope, 237
- Baker, Richard P. : Entry of Peritoxin into Human Red Cells during Hypotonic Haemolysis, 424
- Balogh, R. C. : see under Eganow, B.
- Balavara, Walter X., and Mattson, J. R. : Effect of Rotenone on the Alcohol Dehydrogenase of Yeast Mitochondria, 166-8
- Balderson, Fausto, Broggi, G., and Mancia, M. : Nyctagmus Induced by Unilateral Labrynthectomy affected by Sleep-Wakefulness Cycle, 62
- Bannister, W. H. : see under Wood, E. J.
- Banthorne, D. V., and Lamont, D. M. : Potential Toxicity of Solutions of Dimethyl Sulphoxide, 1296
- Barabas, A. Z., and Kalus, A. S. : Allootypic Specificity of Serum Protein in Inbred Strains of Rats, 155
- Barbatali, Modesto J. : Relationship between Wettability and Adhesion of Polyethylene, 383
- Barber, D. A. : Influence of pH on the Uptake of Phosphate by Barley Plants in Sterile and Non-sterile Conditions, 779

# SUBJECT INDEX

- AAV-1, Association of, with Simian Adenoviruses** (N. P. Raposa and R. W. Atchinson), 1186
- Aberian disease** - see Problems of Scale, 683
- Ability to Smell Solutions of Cyanide: No Simple Pattern of Inheritance in** (K. S. Brown and R. R. Robinette), 406-8
- Abcession in Cotton Explanats: Traumatic Acid - an Accelerator of** (P. E. Strong and E. Krustwagen), 1380
- Absorption Band at 6180 Å at Different Galactic Longitudes: Profile of the Unidentified Interstellar** (H. Seddon), 495
- **Oxidase** (K. Garbett *et al.*), 824-8
- **Line Spectrum of the Quasi-stellar Object 3C 191** (D. F. Falla), 1045
- **and Retention of Strontium in Rats: Reduction of the** (K. Kostal, T. Matković, M. Kadić, R. Marušević and G. E. Harrison), 182
- **of Strontium and Calcium in Newborn Rats: Effect of Calcium and Phosphates on Gastrointestinal** (K. Kostal *et al.*), 1181
- Abysal Organisms: Indication of Cyclic Reproductive Activity In** (R. Y. George and R. J. Menzies), 878
- **Acanthocephala: Production of Ethanol and Succinate by *Moniliformis dubius*** (D. W. T. Crompton and P. F. V. Ward), 964
- Acaricides, Food-chain Toxicity of Systemic, to Predaceous Mites** (R. J. McClanahan), 1001
- **Trifluoromethylpyrimidazole—a New Family of** (D. T. Seggers and M. L. Clark), 275
- Accelerators: Particle** (Edited by R. Kollath), review by M. C. Crowley-Milling, 105
- Accidents in Factories and at Building Sites: More, news**, 914
- Accommodation: Students' Living, news**, 1118
- Acetylcholine from the Cerebral Cortex: Effect of Calcium Ions on the Release of** (M. Randić and A. Padjen), 990
- **Content of Rat Brain, Heart and Intestine: Effect of α-Methyl Dopa on** (V. Bhargava), 202
- **Strychnine and Spinal Inhibition** (D. R. Curtis), 1503
- **is in the Sub-phase: Surface Potential of a di-Palmitoyl Lecithin Monolayer when** (M. Blank and S. O. Essandoh), 286
- **Synthesis: Effect of Cystine on** (J. C. Smith and R. B. Welskopf), 1379
- Acetylene: Properties, Manufacture and Uses, Vol. 2** (S. A. Müller), review by H. W. B. Reed, 1105
- Acetylcholinergic Acid Disposition in Man: Kinetics of** (M. Rowland *et al.*), 413
- Achya basalis: Isolation of a Sex Hormone from the Water Mould** (T. C. McMorris and A. W. Barksdale), 320
- Acid Glycosaminoglycans, Distribution of, in Human Articular Cartilage** (R. A. Stockwell and J. E. Scott), 1376-8
- Acid Phosphatase, Localization of, in Oral Epithelium** (C. A. Squier and J. P. Waterhouse), 644
- **Particulate Localization of, in Fungi** (D. Pitt and P. J. Walker), 783
- Actin in a Molluscan Smooth Muscle: Structure and Organization of** (J. Lowy and P. J. Vibert), 1254
- Actinide Chelates: Uranium (IV) *N,N*-Diethylthiocarbamate** (K. W. Bagnall and D. G. Holah), 623
- Actinomycin, Effect of, on Protein Synthesis by Lymphocytes** (J. E. Kay), 77
- **D, Effects of, on Development in Pupae of *Tenebrio molitor*** (A. M. Chase), 1516
- Action Potentials in the Reproductive System of Plants** (A. M. Sinyukhin and E. A. Britikov), 1278-80
- Actomyosin: Effect of Tropomyosin on the Calcium-activated ATPase of** (M. C. Schaub *et al.*), 635
- N-Acyl-α-glucosamine Derivatives: Inhibition of Lysozyme by** (A. Neuberger and B. M. Wilson), 524
- Adaptation, Light and Dark, in the Isolated Rat Retina** (G. W. Weinstein *et al.*), 134-8
- **The Nature of Perceptual** (I. Rock), review by D. M. MacKay, 900
- Aden: Mid-Ocean Ridge in the Mouth of the Gulf of** (D. H. Matthews *et al.*), 1052
- **A Neopline from the Gulf of** (N. Tabbie), 663
- Adenine Derivative with DNA: Interaction of a Polymeric** (A. S. Jones and N. Taylor), 505
- Adenosine Congeners: Structural Basis for Phosphorylation of** (H. T. Shigeura and S. D. Sempson), 419
- ADP Phosphorylation, Inhibition of, by the Attractyloide of Yeast Respiratory Paraoxide** (V. Moret, L. A. Pinna, M. Lorini and N. Siliprandi), 975
- **3',5'-Adenosine Monophosphate, Role of Cyclic, in the Release of Growth Hormone in vitro** (J. G. Schofield), 1382
- Adenosine Phosphate: Effect of Ionophoresis of, Bleeding Time and in vivo Platelet Adhesiveness in von Willebrand's Disease** (J. Leslie), 1302
- **Triphosphatase of Actomyosin: Effect of Tropomyosin on the Calcium-activated** (M. C. Schaub *et al.*), 635
- **Triphosphatase activated by Magnesium and Superprecipitation of Myosin B** (T. Nihai), 886
- Adenosine Triphosphatase: Electrical Potential Across the Rat Small Intestine Stimulated by** (P. G. Kohn *et al.*), 1395
- **Synthesis of, driven by a Potassium Gradient in Mitochondria** (R. S. Cockrell, E. J. Harris and B. C. Pressman), 1487
- Adenovirus Type 12, Increased Tumour Induction by, in Thymectomized Mice and Mice treated with Anti-lymphocyte Serum** (A. C. Allison *et al.*), 185-7
- **Relationship between the Subunits and "T" Antigens of** (A. C. Hollinshead, B. Bunnag and T. C. Alford), 397-9
- **Tumour Sera by Gel Electrophoresis: Heat-labile Macroglobulin revealed in** (A. C. Hollinshead and T. C. Alford), 399
- Adenoviruses: Association of AAV-1 with Simian** (N. P. Raposa, and R. W. Atchinson), 1186
- Adhesion and Adhesives: Treatise on** (edited by R. L. Patrick), Vol. 1: Theory, review by R. P. Sheldon, 905
- Adhesion of Polyethylene: Relationship between Wettability and** (M. J. Barberis), 383
- **Wettability and** (E. A. Boucher), 1054
- Adhesives: Treatise on Adhesion and** (edited by R. L. Patrick), Vol. 1: Theory, review by R. P. Sheldon, 905
- Adhesive Tapes: Sensitivity of Aerobic Micrococci to DAQ** (L. Jeffries *et al.*), 255-7
- Adiabatic expansion of relativistic Gas: see An Evolutionary Sequence for Strong Radio Sources** (M. Simon and F. D. Drake), 1457-9
- Adipose Tissue Phospholipid in vitro: Incorporation of <sup>14</sup>C-Choline and Tritiated Inositol into Rat** (G. Porcellati), 1189
- Adrenal Gland of a Snake, *Xenodon morranii*: Distribution of the Adrenaline-forming Enzyme in the** (R. J. Wurtman *et al.*), 879
- **after Splanchnic Stimulation: Secretion of a Chromaffin Granule Protein, Chromogranin, from the** (H. Blaschko *et al.*), 58
- Adrenaline-forming Enzyme in the Adrenal Gland of a Snake, *Xenodon morranii*: Distribution of the** (R. J. Wurtman, J. Axelrod and J. Tramaczani), 879
- Adrenocortical Function, Diurnal Variation of, in Hypophysectomized Rats with Multiple Heterotopic Pituitary Homographs** (J. W. Kendall and C. P. Allen), 876

## GETTING ABOUT IN TOWNS

THE Greek gods would appreciate some of the irony which now attends the muddle in Britain on transport policy, but people who have to move about on the surface of the Earth are much less likely to be amused. Absurdity has reached a kind of climax in the past week or so, when Mrs Barbara Castle, the Minister of Transport in the British Government, has been launching a fistful of public documents on road transport at a time at which the nationalized railway industry has been unable to win the consent of the National Union of Railwaymen to a scheme for the efficient working of new rail freight terminals in big cities. To be fair, Mrs Castle has entirely the right ideas about the need to see that the balance which is struck between different forms of transport, particularly road and rail, is determined by rational considerations, most of them economic. So much she announced in her White Paper on transport policy less than a year ago and, even if she is not given to the vocabulary of systems analysis, much of what she has to say would be considered entirely respectable at places like the RAND Corporation. But it is one thing to have good aspirations, and quite another to make them come true. And the truth is that in Britain the ideal of an integrated transport system, which is to be understood strictly in the sense that the several different forms of transport should make their most economic contribution to the process of moving people and goods from one place to another, is still more of a distant goal than a reality.

The way in which energy and zeal are being lavished on the wrong problems is one of the saddest features of this sad state of affairs, as the report called *Cars for Cities* (HMSO, 21s.) illustrates all too painfully. This document is the product of two interlocking committees created three years ago by Mr Ernest Marples, a previous Minister of Transport. To begin with, the object was to see how changes in the design of road vehicles might create problems—or opportunities—in urban transport. Sensibly enough, the two committees have taken a somewhat broader view of their responsibilities than may originally have been intended, even though the handsome document they have produced studiously avoids mentioning trains and subways even as yardsticks for comparison. It is true that the more technical of the two committees, composed largely of engineers and people with practical experience of traffic problems, does have sensible things to say about the advantages of high acceleration for city cars, the potential benefits of segregating goods vehicles from others and the great advantages which may eventually come from various forms of automatic guidance in cities, but most of its effort has been spent on detailed suggestions for the design of small cars capable of carrying up to four people at a time and

usable only within cities. Most of its energy has been lavished on an elaborate scheme, which some will think a fantasy, for constructing in central London networks of elevated roads reserved exclusively for these tiny vehicles. But this is not even a poor solution to urban traffic problems. It is simply a red herring.

All this is evident from the way in which the technical committee, like the still more distinguished steering group which seems to have served in an avuncular capacity, insists that the benefits of tiny motor cars will be marginal unless they are provided with a segregated road system all to themselves. The argument is an elaboration of the simple view that to the road builders, a traffic lane must be at least as wide as the widest vehicle legally allowed to travel on it. But what would be the cost of a segregated road network for tiny cars? And if segregated road networks are within the bounds of possibility, are the tiny cars a more deserving cause than goods vehicles, or buses? On questions like these, both the committees are conspicuously uninquisitive. Instead, there are the predictable and even platitudinous exhortations. The potential benefits of "an integrated design of car, roadway and parking space" are so great that "it is vital to make a real effort" to achieve them. And "a co-ordinated research and development effort directed towards new forms of storage battery, fuel cells and advanced gas turbine engines and indeed any other prime moving device with low noise level and in-obnoxious exhaust should be mounted on a much more ambitious scale than at present". While all this is going on, nobody should be surprised if road traffic in London is found one day to have congealed entirely.

What Mrs Castle's committees should have told her, of course, is that technology as such cannot contribute directly to the solution of urban traffic problems except in comparatively unimportant ways. By now there is plenty of evidence that real improvements in the quality of surface transport for individuals are almost certain to stimulate the use made of roads. As Mr Parkinson would say—and may indeed have said—the number of cars on the roads will increase until the roads are jammed. More accurately, private individuals will tend to use their own cars in cities unless it is cheaper, quicker or more pleasant to use some other form of transport. It does not follow from this, of course, that traffic engineers should abandon as self-defeating their attempts to improve the efficiency of networks of urban roads. On the contrary, they should push on with schemes such as those which now abound for complexes of traffic intersections controlled by computers, for this is the best way of exploiting expensive capital assets

to the full. But if the real objective is a radical recasting of the pattern of urban transport, the solution is much more likely to be found in sociology and economics than in technical innovation pure and simple.

Another of the committees at the Ministry of Transport is, in this sense, a little nearer the mark. On the same day as the appearance of the report on tiny motor cars, the ministry published a report of a study of how the flow of road traffic in British cities, particularly London, might be controlled by the impositions of charges of various kinds (*Better Use of Town Roads*, HMSO, 7s. 6d.). The starting point for this argument is the calculation, not entirely above reproach, that the restraint of private motor cars in cities like London would allow other traffic to move much more quickly and economically. On one version of the argument, for example, a daily charge of 6s. for each private car entering central London would bring about a saving of £5 million a year from improved efficiency—and a cash revenue of the same amount. Even though these arguments are grossly optimistic, they are probably worth more detailed consideration. It is, after all, something to be grateful for that the ministry's committee has retreated from the old impractical idea that all vehicles might be charged an amount identical with the economic value of the use made of the roads. But if the goal is really the "elimination" of the motor car commuter, the ministry has to acknowledge that there will be a serious economic disadvantage in a system in which the grossly inadequate public transport systems now operating in British cities are the best means of transport accessible to all but millionaires.

Here too the ministry has been dazzled by oversimple considerations, most of them arithmetical. It is, however, entirely possible that much greater improvements in the over-all quality of urban transport could be obtained by comparatively easy administrative actions. Recognizing, for example, that most city transport systems are entirely adequate except at the morning and evening periods of peak travel, cheap fares for off-peak travel on public transport could bring great benefits. Comparatively small amounts of money spent on the speed and even the comfort of bus services and subways could bring important gains. Pricing policies which would cheapen the cost of travel within cities along trunk routes could help enormously to put commuter cars at a disadvantage, as could a sharper distinction between trunk routes (usually subway lines) and more local distribution networks (based more often on buses and taxis). Keeping public transport systems running late at night could be an economic gain if, on paper, a monetary loss. Using one part of the transport system to subsidize another is entirely respectable.

But which of the many possible solutions should the administrators try out? On the face of things, this is a daunting question. In reality, however, there is plenty to be done. A much more thorough understanding of how people use city transport of all kinds is an urgent need. Most of the British surveys so far have

been designed to measure the volume of traffic and not to understand why it exists, but only a sensitive appreciation of the function of urban transport will make it easy to divert it into more convenient patterns. Then there is also a need for experiment with administrative measures such as unusual pricing policies for public transport. Certainly there is more reason to hope that intelligent management of public transport policies could do more to rationalize the pattern of city transport than any artificial network of roads for tiny motor cars. In the long run, imaginative policies on transport in cities could help to shape cities into more efficient communities in which urban transport would be obviously a convenience and not a nuisance as well. But this will require that the Ministry of Transport should hold much more rigorously than it does to the view that city transport, public and private, must be dealt with as an integrated service designed to satisfy the needs of real people. In cities, if not elsewhere, there is no truth in the epigram that to travel is better than to arrive.

## NO COMPARISON

THE report of the OECD on the state of science in the United Kingdom and West Germany (see page 9) is something of a disappointment, coming as it does in a series of public documents which has done much to direct the attention of governments to important problems in the administration of science. A part of the trouble seems to have been that the decision to compare the two countries has led to an artificial emphasis on such tangible differences as may be found to exist. The danger that this would happen was appreciated before the study was begun, but foresight has not prevented the two groups of examiners from giving far too much importance, for example, to the structural differences in the machinery for the administration of science in Germany and in the United Kingdom. At the same time the report is curiously unhelpful about differences which are at once striking and potentially important. Why, for example, does German industry contribute more towards scientific research than its counterpart in the United Kingdom? The examiners of the OECD would have had a friendly reception from the British Ministry of Technology if they had been able to supply a pithy answer. No doubt there are some at least in West Germany who would have been equally receptive of a sympathetic explanation why expenditure on university research seems occasionally to have been less productive than it might have been. By paying less attention than it should have done to matters like these, the OECD report has tended to exaggerate the similarities as well as the differences between the two countries.

The study of science policy in Germany and in Britain was also, however, complicated by the importance the two governments attach to science and technology. Both of them are earnest seekers after better science policies, especially just now. The OECD

is quite right in pointing out that each of them gives a different emphasis to the objectives of policy—the British Government, for example, is most of all concerned to win some cash return from science and technology. The two governments have in common, however, the need to grapple with exceedingly complicated problems. Science policy runs into educational policy at one end of the spectrum and into taxation policy at the other. In circumstances like these, broad generalizations are unlikely to be convincing. Thus the way in which the OECD report rightly points to the cramping influence of specialization at British secondary schools will bring comfort to some of those who are engaged in battles to see things changed, but a report like this must necessarily seem somewhat remote and even oracular. Much the same is true of the chief recommendation of change in the administration of science in Britain—the claim that there should be a closer link between the empires maintained respectively by the Department of Education and Science and by the Ministry of Technology. A few years from now there may be a strong case for an amalgamation of these interests, but in spite of the enthusiasm of the House of Lords for this cause two weeks ago, it would be wrong to reunite science and technology under the Ministry of Technology until that recent creation knows much more clearly than at present what kinds of policies to pursue. Indeed, if the Ministry should accept the logic of its recent discovery that Keynes has as much to say as Rutherford about the translation of technology into money, it may grow to be more closely connected with the Department of Economic Affairs than with the Department of Education and Science. Then nobody knows what function the Central Advisory Council on Science and Technology will be able to work out for itself. Will Sir Solly Zuokerman be a co-ordinator or simply a harassed referee? These are fascinating questions, but they cannot unfortunately be answered by appealing to what may be described as recorded science policy. In this sense OECD has probably learned as much from its examinations as have the two countries most concerned.

## DOES CHINA EXIST?

Few people are well placed to know what is happening in mainland China, and one result is that even quite simple travellers' tales are eagerly sought after by those who have been compelled to stay at home. The article by Dr K. Mendelssohn on page 10 is more than a mere anecdote, of course, but it also serves to add another morsel of flesh to the crude skeleton which must at present serve as an appreciation by outsiders of the present condition of science in China. No doubt the Chinese themselves would be alarmed to know how strangely many of their recent policies have seemed from overseas. On the face of things, for example, it is hard to reconcile the policy centred on the communes in the early sixties with the character of technology as it is known in the West. By the same test, it is not

easy to see how the interests of working scientists in China will have been affected by the social phenomenon called the Cultural Revolution. Will they now be better placed to work effectively? Or will they find that too much energy must be spent in the pursuit of orthodoxy? These are important questions, for it is only a matter of time, though perhaps a long time, before Chinese scientists are fully integrated within the international community. It is disappointing that these questions are so hard to answer.

Who is to blame? The most obvious thing to say is that there is no obvious reason why the mainland Chinese should at this stage pay close attention to the international interests of their scientists. They have other fish to fry. Yet there is plenty of evidence in the past few years of a wish somehow to demonstrate that science and technology are flourishing in mainland China. There was, for example, quite open boasting a year ago about the way in which a group of Chinese chemists had been able to synthesize insulin, and, in retrospect, there was plainly plenty to boast about. Although the synthesis of insulin was completed almost at the same time in the United States, it looks as if the Chinese group had to contend with more serious difficulties; a good many of the natural intermediates in the synthesis of insulin were not easily obtainable, for example. It is also understandable that the government at Peking should be eager to point out the cleverness with which technical people have been able to make thermonuclear weapons a mere decade after what seemed at the time to be a great step forward in nuclear technology—the opening of a modest research reactor in 1958. Yet the scientific literature which is now increasingly available, often in translation, shows that these events are not strictly occasions for surprise. There is plenty of talent in the universities and institutes, though there is a long way to go before the research is being carried out on a scale which matches the size of China and the energy of its population.

In circumstances like these, patience is evidently the greatest need. It is too soon to expect that Chinese scientists should mix more willingly with the rest of the world. There is, however, good reason why they should be less suspicious of a continuing relationship with institutions elsewhere. After all, the Chinese themselves must know how much they gained in the fifties from their ability to move comparatively easily to institutes like that at Dubna in the Soviet Union. By now they should also have discovered that even in Western Europe, scientists do not always have horns growing out of their heads. Such exchange agreements as there have been, however, have so far been discouraging. Chinese visitors to laboratories in Europe have kept themselves in isolation. Visitors to Peking have sometimes found themselves kicking their heels in hotels. Language is an obvious difficulty, but only half the story. Is it too much to hope that exchange agreements will function more generously now that the first thermonuclear weapon has been exploded? That would be a curious irony.

## NEWS AND VIEWS

### Uranium In Plenty

THE United States Atomic Energy Commission has now made public the production capacity of the gaseous diffusion plants at which it manufactures enriched uranium, chiefly as a demonstration to industrial interests in the United States and elsewhere that nobody needs to worry about the availability of enriched uranium for power production, at least for some time to come. Inevitably, the AEC has had to provide information about its capacity to manufacture nuclear explosives which has only previously been guessed at. There is, however, at this stage no prospect that the technology of gaseous diffusion will become public knowledge, and the AEC has emphasized its intention that classification should persist.

The way in which the gaseous diffusion plants have been run down in the past six years is also apparent from the statement by the AEC. Electricity consumption at the three plants now operating is running at about 3,000 MW, compared with a peak consumption of nearly twice as much in the early sixties. In its statement, the AEC says that it is at present intended to reduce the operation still further until electricity consumption is running at roughly 2,000 MW by the end of 1968. Even then, when production will be roughly a third of full capacity, the AEC will be able to produce more than 3,500 metric tons of uranium metal enriched to 2 per cent in uranium-235. The corresponding production of uranium sufficiently enriched for the manufacture of weapons would be more than 30 metric tons a year.

The production capacity of the gaseous diffusion plants has been described in terms of the number of units of separative work performed on the isotopes of uranium by different quantities of electrical power (see Table 1). The non-linear character of this relationship no doubt reflects the way in which production is most efficient when the diffusion plants are working below their full capacity. The separative work done in separating isotopes is really a measure of the entropy of mixing of the two products, and in the operation of a diffusion plant the work done to produce a given quantity of enriched uranium will depend not merely on the degree of enrichment but also on the concentration of uranium-235 in the depleted uranium rejected from the plant as tailings. At present the AEC is operating its plants in such a way that tailings contain 0.2531 per cent of uranium-235, which implies that annual production (with electricity consumption running at 3,000 MW) would be equivalent to 2,615 metric tons of uranium enriched 3 per cent or 5,215 tons of uranium enriched 2 per cent.

Table 1. SEPARATIVE CAPACITY OF US GASEOUS DIFFUSION PLANTS AS A FUNCTION OF POWER CONSUMPTION

Megawatts	Annual production (millions of kilogram units of separative work)
2,000	8.9
3,000	5.9
6,000	17.0

In its statement the AEC says that the US government will need "only a small per cent" of the production of the gaseous diffusion plants during the seventies. Now that private operators of power stations in the United States may own their own uranium, the AEC is going to undertake to enrich this at its diffusion plants beginning in 1969.

### British Diffusion

INTEREST in gaseous diffusion for the separation of uranium isotopes has also recently been awakened in Britain. For one thing, work is well in hand with the scheme to prepare the diffusion plant at Capenhurst for the more efficient production of enriched reactor fuel. This work will cost a total of £14 million, and is intended to put the UK Atomic Energy Authority in a position to supply fuel for the advanced gas cooled reactors now being built in Britain—but not yet elsewhere. But there is also talk of the further extension of the plant to provide enriched fuel for power reactors being built in Europe. These schemes raise a number of problems.

The chance that the United Kingdom might be able to sell enriched uranium cheaply enough to compete with fuel from the United States is clearly sufficiently real for meaningful discussions on the subject to be held, but there is also talk of how it would be even more advantageous if an enlarged diffusion plant could be coupled more or less directly to an AGR reactor so as to take the fullest advantage of the high load factors of both types of machines. But if Capenhurst is to be extended so as to produce enriched fuel for reactors in Europe, who is to pay the initial cost? Obviously the AEA would like to see some at least of the capital coming from Europe, although it is hard to see how that could happen without compromising the authority's right—even duty—to keep the technology of gaseous diffusion to itself. But it is also known that the Government as a whole is uneasy about some of the political implications of the scheme. The possibility that export sales of reactors may eventually be determined by the capacity of the potential vender to offer continuing supplies of enriched uranium is never far beneath the surface.

### Computers In Concert

THE British computer industry will be permanently transformed by the proposed merger of two of the principal companies in the field—English Electric and Elliott Automation. On its own merits, the scheme is likely to appeal to shareholders of Elliott Automation, who have not done particularly well in recent years and who will be flattered to know that English Electric has valued their business at more than £41 million. Then everybody concerned will be cheered to know that the Industrial Reorganization Corporation has agreed to lend the joint enterprise £15 million in return for a modest rate of interest and the right to buy English Electric shares six or eight years hence. Evidently the marriage is well blessed, although it seems also to be an open secret that without this handsome dowry from public funds it would have been much less attractive to the proposed partners—both of them have found in recent years that good ideas

are easier to come by than the capital with which to finance development.

The technical advantages of the merger are easily appreciated. English Electric has recently won renown for itself in the design of time sharing computers. It is well placed in Europe and, like Elliott Automation, has established valuable outlets in Eastern Europe. It will be at least a formidable contender for the role of the largest computer manufacturer in Britain—a part now played by International Computers and Tabulators, which has computers worth £40 million on order. But the technical diversity of the merged company is in many ways even more remarkable. English Electric is traditionally strong in power machinery, from diesel engines to electrical generators of all kinds, and may thus provide a ready-made use for many of the process control devices which have been developed by Elliott Automation. At the same time, the experience of Elliott Automation with micro-circuits and with smaller computers may be useful to English Electric. Probably the biggest danger in the new arrangement is that the merged company may repeat the error of Elliott Automation in recent years of biting off more than it can chew.

## Plasma Instabilities

THE Science Research Council has set in motion a study of plasma physics in Britain. According to the official notice issued by the Plasma Physics Panel, its aim is "to provide a factual basis for forecasting research needs in this subject, as indicated both by university departments and by actual and potential applications to industry and technology". The review is being conducted by Dr P. A. Davenport of the Culham Laboratory of the UKAEA.

Dr Davenport has started by writing to universities to determine what courses of training in plasma physics are available. Most of these are well known to the SRC, but Dr Davenport is hoping that any he has missed will come forward to be counted. The inquiry also covers research in universities and government laboratories, and was originally initiated by the SRC to enable it to determine what areas of plasma physics should be fertilized with grants. The survey will also include an assessment of the applications of plasma physics in industry.

The review follows another rather different review of plasma physics. This was carried out by the Ministry of Technology, to determine the future of the AEA fusion research programme. The minister, Mr Wedgwood Benn, recently hinted at the results of the survey: "... this is a very difficult problem... the AEA work is excellent in every way, but prospects of fusion producing power are less hopeful than before. Fusion is not really likely to meet our needs in the near future... the AEA was right to establish Culham Laboratory, but the problems have got worse, and with the fast reactor coming along..." No decision has been announced, but it is clear that Culham sits somewhat unhappily beneath the Mintech umbrella, large though it may be. Pay-off in three years is the ministry war-cry these days.

That Culham finds itself in this position is something of a historical accident, a result of the separation of science from technology in Whitehall. It hardly needs a wild stretch of the imagination to see Culham

under SRC control, and then at least the pressure to produce a fusion reactor next week would be lessened. The change might well be more a book-keeping operation than anything else, and need cause little disturbance to personnel. By a nice irony, the notice setting up the SRC review is issued from Culham Laboratory, and is signed by the director, Dr R. S. Pease. In another guise, he is chairman of the Plasma Physics Panel of the SRC.

## Another Look at Southern Skies

THE agreement between President Johnson and President Frei of Chile to build a large optical telescope in the Chilean Andes was clearly no empty promise inspired by the camaraderie of the Punta Del Este conference. Further details now available indicate a firm commitment to go ahead with the project which will make the Cerro Tololo observatory one of the few major observatories in the Southern Hemisphere. Thirty-six and sixty inch instruments are already under construction there. Thanks to the lack of city lights, dust and industrial contamination, the site is perfect for an observatory, and the absence of man-made contamination is aided by particularly favourable meteorological conditions.

The new telescope is to be paid for jointly by the National Science Foundation and the Ford Foundation, through the Association of Universities for Research in Astronomy, Inc. The instrument will be essentially the same as that being designed for Kitt Peak National Observatory, near Tucson, Arizona. Both are to be 150 inch instruments, and it is expected that design duplication will greatly reduce costs. This means that no fewer than three 150 inch instruments will be built to virtually the same design, for it was recently announced that the Southern Hemisphere Telescope to be built in Australia would be based on the Kitt Peak design. Costs for that instrument, to be paid jointly by the SRC and the Australian Government, are estimated at £4.4 million (\$12.3 million), while the Chile telescope is to cost \$10 million.

## Turtles come to Britain

TURTLES are animals of tropical and sub-tropical waters, but sometimes they are stranded on British beaches. The first record of a landing is due to Sibbald who, in 1684, was told by a worthy man of Orkney that turtles were sometimes captured there; between September 1938 and February 1939 eleven turtles were stranded in Great Britain and Ireland. Since then receivers of wrecks and HM coastguards have been keeping records for the British Museum (Natural History), which is anxious to collect as much information as possible about these strandings. To help turtle catchers identify finds, the museum produced a booklet *Stranded Whales and Turtles* which is now superseded by *British Turtles* by L. D. Brongersma, director of the Leiden Museum. Anybody finding a turtle is requested to inform the British Museum by telegram immediately, and if sending the specimen itself to send it alive—turtles are extremely difficult to kill humanely except by hypodermic injection.

Turtles are known to travel great distances—for example, from the Brazilian Coast to the island of

Ascension—between feeding and breeding areas, but such migrations take place within one climatic zone. It is remarkable, as Mr Brongersma points out, that the animals should reach Northern Europe where the climate is unsuitable for a long stay, and where they cannot breed (the temperature is far too low).

Most of the animals found in British waters seem to come from the Western Atlantic Ocean and the Gulf of Mexico. Kemp's Ridley, *Lepidochelys Kempi* (Garman), one of the five species described in *British Turtles*, breeds only in the Gulf of Mexico, and may pass through the Florida Strait to the east coast of America. It sometimes continues its voyage from America to Europe, partly carried along by the Gulf Stream. The age of some of the specimens found suggests that hurricanes in the Caribbean area could sweep some very young turtles out into the ocean, where they lose their bearings and then just follow the current. Some specimens have lacked one of their front flippers, which implies that they would only have been able to swim in circles—clearly they must have been swept along by the current. The journey to Europe seems to take between thirteen and seventeen months. Although protected by their shells, the turtles are still in danger of having flippers bitten off by sharks or sliced off by propellers of ships, so that the specimens which finally reach the British Museum are not always complete.

## Structure and Reactivity of Ribonuclease

from Professor E. A. Barnard

THE recent determinations of the three-dimensional structure of ribonuclease offer an unusual opportunity for insights into the molecular basis of enzyme action, and were the background for the international symposium held at the State University of New York at Buffalo between May 31 and June 1.

To begin with, there was a correlation of the determinations of the structure itself. Models and maps of the 2 Å structure of ribonuclease A due to G. Kartha, J. Bello and D. Harker and that of ribonuclease S due to H. W. Wyckoff and F. M. Richards (at 3.5 Å) were compared side by side. The very high degree of agreement between the structures was remarkable, considering the use of two protein forms in different heavy atom derivatives and in very different solvents. Most of the differences occur, as expected, in the regions on both sides of the bond (20–21) that is cleaved to form the ribonuclease S derivative. C. H. Carlisle who, using quite different derivatives, has obtained a map of ribonuclease A at 5.5 Å, showed that this was compatible with the Kartha's map with a transposition to a corresponding origin of co-ordinates: this map should lead to the same structure when taken to higher resolution.

A good deal of attention was paid to evidence on binding properties. Both the Roswell Park group (Kartha and colleagues) and the Yale group (Wyckoff, Richards and colleagues) showed that one bound ligand, defining the active centre regions, can be located in a cleft. The Yale workers specified the binding of inhibitors containing iodouracil. Several participants related the specific binding of di-anion inhibitors to interactions at a cluster of histidine and lysine side chains. G. G. Hammes interpreted evidence of relaxa-

tion rate to show discrete steps in the binding, involving histidines and (by presumption) a carboxyl.

There was much less agreement on the mechanism of catalysis. Different hypotheses by B. R. Rabin, G. G. Hammes and H. Witzel were separately put forward as consistent with the structure. It seems not to be possible to specify from the X-ray evidence the type and the extent of structural change which occurs on binding, chiefly because a ligand bound to the active site has so far always been necessary for crystallization. This, in itself, suggests a more motile structure for the free enzyme.

Some new directions of work became clear at this conference. H. A. Scheraga forecast the total computation of the structure of proteins such as ribonuclease and lysozyme, using their sequences and the minimization of energy. This bold approach has been applied so far to gramicidin S, oxytocin and, now, to two regions of ribonuclease. The method should yield the structure the proteins would possess if isolated, so that its validity has not yet been fully tested. In comparative studies, C. H. W. Hirs showed that pig pancreatic ribonuclease is a series of glycoproteins. E. A. Barnard, M. H. Gold and E. N. Zendzian reported a new study of the distribution of pancreatic ribonucleases through the vertebrates, and presented evidence of reactivity and specificity which shows that the active centre is similar. The active centre specific labellings they obtained point the way to phylogenetic sequence comparisons, but the time is clearly still distant when it will be possible to make a full comparison of three-dimensional structures in this series.

## Circular DNA

from our Correspondent in Molecular Biology

MUCH interest has in recent years been generated by the discovery of circular DNA in viruses, and more recently in mitochondria from a variety of cells. This DNA is fully double stranded, and has been shown to be covalently cyclic. The properties innate in such a structure have been investigated by Vinograd and his associates. They arise from the topological restriction that, for a given molecular weight, the number of turns of the two-stranded helix is fixed. This confers on the molecule an enhanced resistance to denaturation, and hydrodynamic properties which differ from those of linear native DNA.

Good evidence was obtained earlier that the normal form of mitochondrial circular DNA is supercoiled, and shapes were observed in the electron microscope which were best described as being like pretzels. Vinograd and his group showed that when a single break is introduced in one strand, or when a small degree of denaturation is provoked, the supercoil is able to unwind and the molecule reverts to the untwisted circular form.

Radloff, Bauer and Vinograd (*Proc. US Nat. Acad. Sci.*, **57**, 1514; 1967) have now devised a striking method for the separation of intact circular DNA from the linear and the damaged circular species with which it is extracted from the cell. The principle involves the binding of a dye, ethidium bromide, which belongs to a class of planar conjugated molecules now generally held to be capable of intercalating, or sliding between adjacent bases, in a helical DNA. There is

both *a priori* and experimental evidence that such an insertion must stretch the molecule and give rise to some degree of unwinding of the helix. When the dye is added to the circular DNA, the superhelix untwists, in order that the number of turns in the primary helix may remain invariant. With addition of further dye, a superhelix of the opposite sense begins to form, so as to take up more slack, until a rather rigid structure is produced which cannot deform sufficiently to accommodate more dye. The circular form thus binds substantially less dye than the linear form. But when a dye is attached to DNA, there is a decrease in the density of the molecule; consequently the circular DNA saturated with ethidium has a greater buoyant density than saturated linear DNA which contains more dye, and is widely separated from it by sedimentation in a caesium chloride density gradient. Excellent fractionations are achieved, which must exclude even molecules with a single break in one strand.

Electron microscopy on preparations from HeLa cells reveals, in addition to the circular molecules previously encountered in mitochondria (mean length 4.8 microns), some large supercoils which are multiples of these, and also some very small and polydisperse circles (0.2–3.5 microns). These could code only for between 200 and 3,500 amino-acids, and their function is unknown. It will be interesting to establish whether they are universal constituents of mammalian cells.

## Genome Transcription

from our Correspondent In Cell Biology

In bacteria, unlike eucells, the replication of the DNA genome goes on throughout virtually the whole of the cell division cycle. This implies that transcription and replication of DNA occur simultaneously. Indeed, it has been suggested that the basal level of enzyme synthesis could be controlled by a coupling of these processes, with transcription occurring only at or near the replication point where stretches of single stranded DNA might be expected. This is not a universal mechanism, however, for, as Maaloe and Kjelgaard (1966) showed, ribosomal, transfer and some species of messenger RNA are made throughout the whole cell cycle.

Several important features of the pattern of DNA transcription and replication during the division cycle of *Escherichia coli* have recently been determined by Cutler and Evans (*J. Mol. Biol.*, **26**, 91; 1967) using an ingenious technique they devised (*ibid.*, p. 81) for the isolation of segments of the *E. coli* genome. Synchronously dividing cultures of *E. coli* were fed pulses of 5-bromouracil at different times throughout the division cycle. If the population is sufficiently well synchronized, all cells will have the same region of DNA labelled during any one pulse. The labelled cells are then collected, their DNA extracted and sedimented in a density gradient which separates the denser 5-bromouracil labelled DNA from the rest. The various DNA fractions labelled at different times in the cell cycle fail to hybridize with each other to any great extent; thus they appear to be unique segments of the genome.

Cutler and Evans have been able to measure the amount of RNA which is transcribed off each of these segments at particular times in the cell cycle by the determination—using a  $P^{32}$  pulse labelling technique—

of the amount of RNA synthesized during the cell cycle of a synchronous culture that will hybridize with each DNA segment and which is therefore homologous with it. They find that the entire genome is being transcribed continuously but that the levels of transcription of a particular segment show characteristic fluctuations during the cell cycle.

It is interesting that a high level of transcription of one region is usually accompanied by high levels for all the other segments. How this co-ordination of transcription of the whole genome is achieved remains to be seen. There is some evidence that control of ribosomal and/or transfer RNA transcription may be related to the position of the DNA replicating point, but this is not the case for most of the genome.

One most interesting observation is that two separate segments of the genome are complementary to 16S and 23S ribosomal RNA and most species of transfer RNA. This may mean there are two distinct sites containing the genes for these RNA species although the inherent limitations of hybridization experiments make this interpretation equivocal.

## Can Algae utilize Methane?

from our Correspondent In Microbiology

REVIEWING hydrocarbon fermentations and their industrial application, A. E. Humphrey (*Biotech. Bioeng.*, **IX**, 3; 1967) writes, "Until recently, the primary industrial concern with hydrocarbon microbiology was in connexion with oil prospecting, corrosion problems and formation of a microbial sludge in jet fuel tanks". The scope of hydrocarbon microbiology has expanded rapidly in the meantime and currently the quest is for means of exploiting this microbial activity commercially. Propitious reports of the use of microbes in the partial refining of crude oil fractions and in the production of edible yeast and several biochemicals from hydrocarbons provide a great stimulus for continued research and development.

A report from Dr Lennart Enebo working at the Royal Institute of Technology in Stockholm (*Acta Chem. Scand.*, **21**, 625; 1967) may charge the interest in these matters still further. While studying the growth of photosynthetic sulphur bacteria in different gaseous environments Dr Enebo isolated the green alga *Chlorella* from highly reducing enrichment media in which carbonate and methane provided the carbon sources. Passage of the alga on a glucose medium led to an almost complete, but not total, elimination of the associated microflora. The addition of high quality methane to the carbonate medium culminated in a 35–45 per cent enhancement of algal growth. The grounds for believing that the alga assimilates the hydrocarbon hinge largely on two points. First, the alga excretes various metabolites which are likely to inhibit the growth of methane oxidizing bacteria. Second, free oxygen is produced by algal cultures growing in an atmosphere of 100 per cent methane and it seems reasonable to suppose that this may act in the oxidation of the paraffin to methanol. The subsequent assimilation of  $C_1$  units as carbon dioxide or their incorporation into sugar phosphates has been postulated but not proved. Enebo's claim for methane utilization by *Chlorella* is supported by the fact that he was unsuccessful in demonstrating other methane

oxidizers in his algal cultures. It is possible, however, that the small residual contamination may exercise an effect on algal growth by oxidizing extracellular metabolites produced by the alga. This process would depend on the oxygen derived from algal photosynthesis and would produce carbon dioxide for fixation. Other investigators have found that methane fermenting bacteria will grow on methane alone, although here also carbon dioxide may function as a "primer" for the system (Wolnak *et al.*, *Biotech. Bioeng.*, IX, 57; 1967). Unfortunately, Enebo does not record the absolute carbon requirement of his *Chlorella* strains.

It would be premature to dwell on the technical value of this newly discovered methane assimilating system, but, with growth optima established and the selection of suitable strains, several possibilities might be explored. Enebo indicates an application for gas exchange in closed systems where oxygen enrichment is needed and the production of algal mass on a methane-carbonate basis, even under anaerobic conditions. Although sound economically, few attempts have been made to produce food by fermenting methane and in part, to quote Humphrey further, "The arguments against such a process stem from toxicology and consumer-acceptance problems". The algal system may prove to be an attractive proposition to those interested in this technology.

## Cows as Subjects

THE National Institute for Research in Dairying at Shinfield near Reading is one of the largest research establishments financed by the Agricultural Research Council, with a staff of about 450, more than 800 acres of farmland and 500 cattle. Since the foundation of the institute in 1912, it has been closely associated with the University of Reading, which provides its governing body.

Although the institute is concerned primarily with helping farmers and dairymen to solve their practical problems, a surprising amount of fundamental research is done there. The chemical microbiology department, for example, is working on the antibiotic nisin, discovered at the institute, in the hope of relating the structure and molecular size of nisin to its antibiotic properties. The molecule of nisin seems to polymerize readily, and it may be that the monomer is the active form. The department has also carried out some work on the activity of rennin, including preliminary work on its structure.

The more practical side of the work of the institute includes fundamental studies of cheese and the cheese-making process. The institute has one of the two sterile cheese vats in the world, and these have made it possible to produce cheese using only rennin and a pure "starter" organism. It seems that the character of a cheese is determined chiefly by the nature of the bacterium used to start the process of fermentation. The other organisms which contaminate the bacteria used commercially are not necessary to the process and probably give rise to the "off-odours" which can mar the quality of cheese.

The two farms belonging to the institute are used for studies of the growth and feeding of cows raised under various controlled regimes. The institute also maintains a herd of pigs, some of which are raised under germ-free conditions.

## Parliament in Britain

LORD WINTERBOTTOM, Parliamentary Secretary, Ministry of Public Building and Works, said that progress on the scheme for a National Reference Library for Science and Innovation had suffered a severe set-back because the Greater London Council had discontinued negotiations on the South Bank site for the library, which the council now required for an urgent purpose of their own (undisclosed). The minister was now seeking for a suitable alternative site for the library. The present situation was entirely unsatisfactory, since that part of the library which is in Whiteley's building at Bayswater is thoroughly unsuitable for the work. One or two possibilities in London were being investigated and Lord Winterbottom agreed that the matter is urgent and that good access by public transport and, if possible, a central location of the site selected are important. (Question, House of Lords, June 22.)

LORD BESWICK, the Parliamentary Under-Secretary of State for Commonwealth Affairs, said that there is no evidence, either from research carried out in the United Kingdom or from the study of the results of tests held in the United States, of damage to health from sonic bangs. Damage to buildings varies with the intensity of the bang, but soundly constructed buildings are not affected by bangs of the kind which a supersonic transport aircraft might be expected to make. For operational reasons, the Concord civil aircraft will not reach supersonic speed until at least 100 miles after take-off. (Question, House of Lords, June 19.)

THE Iron Casting Industry (Scientific Research Levy) Order 1967 was approved by the House of Lords on June 19. It imposes levies on the industry to finance scientific research carried out by the British Cast Iron Research Association when the statutory levy introduced under the Iron and Steel Act 1953 ceases with the repeal of that Act on July 28. The levies are expected to yield about £200,000 a year and this will enable the research association to qualify for a grant from the Ministry of Technology of about £80,000 a year. Lord Shackleton, Minister without Portfolio, referred to the initiation by the association of the research which led to the production of spheroidal graphite cast iron, but said that further economic advantages were expected to arise from increased efficiency rather than from innovation, particularly in melting, moulding materials, methods of automatic control, and improvement of working conditions in the foundries.

THE Prime Minister, Mr H. Wilson, declined to appoint a Minister of State in the Ministry of Technology solely concerned with the development of the technology of the sea bed. He did not think that a full-time ministerial appointment could be justified, but agreed that a major marine science programme could be sustained on its own economic merits. Mr Wilson agreed that the time had come for a much wider investigation of marine technology and science and this was one reason for establishing the co-ordinating committee for scientific research. (Question, House of Commons, June 22.)

# Tale of Two Countries

The OECD has already produced reports on the condition of science and technology in several member countries as part of a systematic review of science and science policy. Its most recent venture is a comparative study of science policy in the United Kingdom and in West Germany.

THE possibility that science policy in European countries may be changing more quickly than the Organization for Economic Co-operation and Development can produce reports is one of the impressions created by the latest in the series of reviews of national science policies—this time a comparative study of affairs in the United Kingdom and in West Germany (OECD, \$5.50, 32s., 22 francs). But the document is also valuable as a proof that the two countries have in common not merely size and economic prosperity, but problems as well. There will also be great, if recondite, interest in the evidence given by officials of the two governments at the "confrontation" arranged in Paris at the beginning of March 1966. Many of the hopes and justifications then presented have since been falsified by events.

The notion of a comparative study seems to have been prompted by the statistical similarity of the two countries. In area, for example, they differ by 1.6 per cent and in population (in 1964) by 6.8 per cent (with West Germany slightly the larger on both counts). In 1962 and 1964, the GNP of West Germany was roughly 10 per cent greater than that of the United Kingdom, but the two countries differed sharply in how they spent their wealth—the United Kingdom spent more than West Germany on private consumption (65.5 per cent and 57.6 per cent of the GNP respectively) and less on investment in buildings and machinery (16.2 per cent and 25.4 per cent respectively). The United Kingdom spent more than West Germany on research and development in 1962 (see Table 1), but the difference is not substantial when the cost of military research and development is left out of account. The contribution of the two governments to civil research and development was substantially the same, but British industrial companies seem to have been spending rather more of their own funds on research and development than their counterparts in West Germany. There is a similar pattern in the distribution of effort, measured in money terms, in 1964 and 1965, for which the OECD quotes figures which have been compiled from its own surveys. The report points out that research and development expenditure is increasing rapidly in both countries, and that the figures it quotes may differ because of differences in interpretation—the British figures for university research and development do not, for example, include expenditure by the research councils on units which are closely associated with universities.

The report points out that government support for civil research and development, in both countries the source of more than a third of all spending, is divided among a number of agencies—in Germany between the Federal Government (which maintains a Ministry of Scientific Research) and the Länder governments (which support the universities), and in Britain between the Ministry for Education and Science and the Ministry of

Technology. In the circumstances it is not surprising that the two teams of examiners which undertook the separate study of the two countries should have given a good deal of their attention to problems of co-ordination. On the whole, the report takes the view that co-ordination comes more naturally in West Germany than in the United Kingdom. The report is particularly pleased with the way in which organizations such as the Deutsche Forschungsgemeinschaft and the Max Planck Gesellschaft zur Förderung der Wissenschaften, supported as they are by public funds, are nevertheless able to function effectively in all fields of science.

Yet "co-ordination at government level" is "equally urgent in both countries", in Britain because of the way in which responsibility is divided between two ministries, one of which (the Department of Education and Science) is responsible not merely for research but also for the still larger expenditure on education of all kinds. One possibility going through the minds of the examiners was that the Council for Scientific Policy might be given a more powerful part to play, outside the narrow confines of the Department of Education and Science, but Sir Frank Turnbull, then Deputy Secretary at the Department of Education and Science, argued eloquently against such an arrangement on the grounds that "we believe that in our system of Government it is best to have scientific advice tendered directly to the minister who is responsible for a given field". He was speaking, of course, before the formation of the Central Advisory Council on Science and Technology under Sir Solly Zuckerman.

In West Germany, according to the OECD report, the existence of a central policy making body (the Wissenschaftsrat), formally required to give advice to the Federal Government as well as to the governments of the Länder, is a logical arrangement. Nevertheless, the argument goes, the way in which funds for the support of research are channelled through outside bodies means that the German Government can rarely initiate new developments. Instead, it must function as a "responsive" agency. Things are complicated by the way in which the Wissenschaftsrat cannot be sure that its recommendations on policies which must be implemented by the Länder governments will actually be carried out. Nevertheless the committee has embarked on an attempt to draw up a comprehensive plan for the development of science and technology in West Germany, and the OECD examiners are clearly delighted with the way that project is going.

By comparison with the Government of West Germany, the British Government seemed to the examiners to be preoccupied with efforts to increase productivity and to apply the results of research industrially. German interests were more often concerned to "catch up with the international development of science in certain fields and to implement a nationally co-ordinated development of the educational system".

On education, the OECD examiners have come down heavily against specialization in the schools, which seems to have been most marked in Britain. Although the examiners were impressed with what they describe as the "efficiency" of university education in Britain, they argued in favour of a lengthening of the university course from three to four years. In Germany, too, there

Table 1. RESEARCH AND DEVELOPMENT IN THE UNITED KINGDOM AND WEST GERMANY (£1 = DM. 11.20)

	United Kingdom	West Germany
Total (£ million)	657.7	404
Percentage of GNP	1.3	2.3
Total civil (£ million)	412	367
Government spending (total)	378	185
Government civil spending	183	148
Private sector	290	219
Total spent in universities	22	78

is a need for longer courses of study. The German engineer schools are held out by the examiners as a good example. The OECD report emphasizes that in both countries, problems of scale and of rapidly increasing size are only now becoming apparent, so that changes of structure and of policy will have to be continuous and rapid in the years ahead.

In general, the examiners decided that "the relationship between the scientists and government, the degree of common thinking and reciprocal understanding", are more highly developed in Britain than in Germany. On the other hand, there is a better appreciation of "the importance of science and scientific training in industry and in the general public".

## Science in China

by

K. MENDELSSOHN

Department of Physics, University of Oxford,  
Parks Road, Oxford

In the last few years the development of science and technology in China has gone on apace, and seems to be linked with political development. Dr Mendelsohn has been there three times in the past seven years.

WHEN at the turn of the century the tottering Manchu Dynasty disintegrated, China had seen remarkably little change for six centuries. One of the main reasons was the extreme conservatism of her rulers. The Manchus, being strangers and, in Chinese eyes, semi-barbarians, had done everything to fit in with the accepted mode of Chinese life and, in fact, held on to tradition more tenaciously than the Chinese themselves. The educational system, too, remained firmly based on the Chinese classics which in the public examination system provided the only passport to the mandarinship. Coupled with this attitude was a pronounced xenophobia and a strict prohibition on Chinese seeking to leave their country. Only after the inroads made by Western powers, beginning with the opium war and with the establishment of the Treaty Ports, did knowledge of Western technology start to seep gradually into the country.

After the establishment of the republic in 1911, some well-to-do Chinese began to send their sons to Europe, America and, above all, to Japan to acquire some technological and scientific training. In China itself, university study in science commenced only in 1920. From the very beginning it was hampered, however, by the ever increasing unrest and the incessant campaigns which the various war-lords fought against each other. At the same time the Japanese occupation of Manchuria was gradually increasing, leading in the end to the full scale invasion of China.

When at last in 1949 the present regime extended a unified rule over China, a large proportion of the few scientifically trained Chinese had either perished or left the country. In a much devastated China with a population which had hardly emerged from a medieval feudalistic society, technological training had to start from scratch. In the beginning the Russians rendered a good deal of help by sending experts into China and by accepting Chinese students into their own universities and technical training institutes. When visiting Moscow in 1957, I learned that my Soviet colleagues were indeed much impressed with the ability and single-minded devotion to work of their Chinese students.

At the time of my first visit to China in 1960, the Russian experts were just beginning to leave. Then, as well as in later years, my Chinese colleagues always acknowledged fully the help which the Russians had given to them, although there were other aspects of the withdrawal, such as leaving factories half finished, which were a severe blow to China.

Russian influence also left its mark on the organization of education and research, resulting in a pattern which remained largely unchanged until the cultural revolution of last summer. While certain features of this pattern were modelled on the Soviet example the Chinese departed

right from the beginning in a number of important aspects. Comparatively little is known about the detailed plans for the impending changes in scientific training, but I was given a certain amount of information by Chinese scientists visiting this country in the course of the last year and particularly on my third visit to China in September and October 1966. Something about these future developments will be said later, after dealing with the state of affairs which has obtained until now.

The Chinese student enters his university after a general education at a school which has given him no specialized training. The university science course takes from 5 to 6 years, and the first 3 years are spent on a very thorough general study of the student's subject. There is a certain amount of specialization in the remaining years with a research project in the last one. The course ends with a final examination but no degree is awarded. The student then lists ten choices of employment arranged in order of preference, and the authorities, when placing him in a job, will take this into account as well as his ability and performance at study. One of the difficulties which arose was that the older universities with an established reputation were naturally inclined under this system to secure the best pupils for their own staff positions, leaving the lesser grades for the many newly established centres of learning. In the end a new scheme was introduced which was designed to overcome this drawback. Each of the older universities was made responsible for a number of new ones and the success of each of these groups was then assessed together. This forced them to send some of their good students to these new establishments in order to give them a good start. My Chinese friends assured me that this method had proved very successful.

Another important feature of the Chinese system of higher education is that technology, medicine and practical law are not included in university studies. Here the reason is that in a rapidly developing country an enormous number of engineers, doctors and legally trained administrators will be required, and that inclusion of all these students would have produced a severe imbalance of the university faculties. Instead, all these people are educated at specialized institutions. Taking, for instance, the case of a physicist, we would find the student at Peking University if his aim is to study the fundamental aspects of the subject. If, on the other hand, he is more interested in applied physics, he would turn to one of the technical universities, such as Tsinghua or Hangchow, for his training. Finally, the specialist will study at one of the institutions devoted to a strictly limited field, as, for instance, electronics or hydraulics. In these the specialist subject is not only taught but all the applied research going on in the field is also carried out. Generally speaking, for all studies, except the most fundamental aspects,

A Red Guard at the control desk of a fully automated nitrogen fixation plant near Shanghai (1966).

much stress is laid on close co-ordination between basic research, development and production. Great care is taken that the technical managers of factories are in frequent consultation with these research institutes and they are kept informed, through frequent conferences and visits to other establishments, of the current state of their field throughout the country.

Much of the fundamental research is carried out in the institutes of the Academia Sinica which, at least in its original pattern, is modelled on the Soviet Academy of Sciences. Like the latter, the Academia Sinica comprises, apart from the natural sciences, arts subjects such as literature, history and economics. The scientific institutes are by now well equipped for advanced research, and last October at the Institute for Solid State Physics I was shown superconducting solenoids of niobium-zirconium and of niobium-tin made of wires manufactured in China. There was also equipment for making artificial diamonds which are of similar size and quality as those produced in Western countries.

Staffing still presents a serious problem although now a new generation of scientists and technologists trained in China is becoming available. In the early years, at the time of my first visit in 1960, the whole teaching burden was carried by a small number of men who had been trained between 1920 and 1940, mostly abroad. They were getting old and were, in addition, terribly overworked. A few years later these men had largely moved into administrative positions and their place was taken by the next generation trained in China as well as in the Soviet Union. I was much impressed not only by their degree of competence and ability but also by their excellent knowledge of current research outside China. It frequently happened in discussion after my lectures that they would make reference to results or theories published in the *Physical Review* in the last few months.

There have often been reports in the West of the detrimental effect which insistence on political studies or time spent on parades or demonstrations have had on scientific and technological progress in China. Of this I have seen little. If, indeed, my Chinese colleagues have spent some of their time in this way, they seem to have shouldered this burden in their stride. In fact, judged by the state of affairs in October 1966, scientific and technological progress has been very remarkable

since I saw it first, 6 years earlier. Technological products are usually a pretty good guide and the stage has now been reached when Chinese industry can manufacture practically anything that the West can produce.

In 1960 there existed little in the way of modern factories. It was the period of the much ridiculed backyard industry when I saw girls winding with their bare hands transformers for the agricultural grid. This operation was carried out in an agricultural commune where hardly the simplest machine tools were available. In the open, among horses, ducks and chickens, boys and girls were sitting on the ground, cutting out the transformer housing from sheet metal with hammer and chisel. Miraculously, in the end the finished transformers appeared, complete with cooling coils, and ready for dispatch. Admittedly, productivity was miserably low, but it has to be remembered that it was greater than no productivity at all, which would have been the case without these small plants. A rather more important aspect, and possibly the salient one, is the industrial training which these places provided in an otherwise completely agricultural society. The boys and girls who learned their trade in this hard and exacting school in the end provided the foremen for the factories which were being built at the same time.

Two and a half years later I visited the first of these new factories, one of which made excellent precision grinding machines for a budding machine tool industry. Some of the new factories were equipped with Russian machinery, but by now this has been supplemented or even replaced by excellent Chinese made equipment. The early sixties saw the rise of Shanghai to one of the largest manufacturing cities in the world. Its present population is somewhere between seven and ten million. It is now surrounded by a number of new satellite towns, all with modern blocks of flats and shopping centres, to accommodate the rising industrial labour forces.

By now Chinese manufacturing capacity has shifted into high gear. There are, first of all, the standard products of an industrial power such as ocean going ships, air conditioned and diesel driven trains, cars, buses, trucks, electric generators and gas turbines. Beyond this there is the manufacturing equipment; machine tools of every description and a lot of ancillary plant such as arc melting furnaces, vacuum deposition units and electronic gear,

Using an electron microscope made in China.

to mention just a few. Even more impressive are the highly sophisticated products which can only be found in a fairly advanced technological society. These are things like electron microscopes, industrial spectrographs, precision balances, single lens reflex cameras and computers.

I have mentioned these things because they seem to provide a better appreciation of the underlying scientific and technical training than educational statistics. They also show that this training must be of high standard and broadly based to be able to account for the great variety of products. The most remarkable aspect of this technological advance is the fantastic speed with which it has been achieved. The complete change of the technological scene which I witnessed in the interval of only a few years is almost unbelievable.

One of the main springs of the development clearly is the unbounded enthusiasm with which the whole population has set its mind on the rapid reconstruction of the country. When in 1949, after a century of chaos and humiliation, China emerged again as a sovereign power, the Chinese could hardly believe that the age of war-lords, invasion and famine was over and had given way to stability and security. Once they had realized this unbelievable good fortune, they threw themselves wholeheartedly into the task of perpetuating and improving this new state of affairs. They were told that the creation of a modern technology was the most important way in which the country could be strengthened and the standard of living could be raised. On my second visit my colleagues introduced me to Mao Tse-tung and Foreign Minister Chen Yi. Both of them, in their welcome to me as a foreign scientist, emphasized the need for China's scientific and technological development. When I mentioned that they were progressing rapidly, Chen Yi brushed this aside, saying that China was technologically still backward and must learn quickly. This attitude of not being content with the present achievements and of spurring on to still more rapid advance is the

note met in all educational establishments as well as in the factories.

This is not the place to discuss in detail the meaning of the cultural revolution, but it is quite apparent that the pace is not slackening but, wherever possible, is increasing. This emphasis on rapid development is particularly held by the young generation, who cannot remember the bad old days and who have grown up in security and relative comfort. The call for "continuous revolution" means, above all, the resolve to continue the effort of the last seventeen years. That no break in the progress of science and technology is envisaged is clearly shown by a special provision in the programme of the cultural revolution, the famous decision of the Central Committee of the Chinese Communist Party of August 8, 1966. In point 12 it says: "Special care should be taken of those scientists and scientific and technical personnel who have made contributions. Efforts should be made to help them gradually transform their world outlook and their style of work". Clearly the emphasis is on the term 'gradually' which is a firm directive not to interfere with the development of science and technology.

In the early summer of 1966 a physics colloquium was held in Peking, and while other papers were published under the authors' names we find one coming from the research group on the theory of elementary particles, Peking. This styling is in full accord with the tenets of the cultural revolution which deprecates striving for personal fame. The title of the paper is *Research on the theory of elementary particles carried out under the brilliant illumination of Mao Tse-tung's thought*. It contains a very serious and quite impressive attempt at solving the internal structure of elementary particles in which the successive steps are copiously underlined by reference to Mao's works. The essential feature is an internal wave function describing the structure of the hadron and the advantage of this approach is that correlation of the theory with experimental results can be made without having to make assumptions on the unknown dynamics operating inside a particle. In true Maoist language the relevant chapter is headed "How can you catch tiger cubs without entering the tiger's lair?".

New and far reaching plans for a change of the educational system were, in fact, the very first sign of the cultural revolution. In 1965 already Chinese colleagues visiting Britain told me about this impending move and we can expect that, when the dust has settled after the parades and wall posters, these proposed reforms may be implemented. The basic feature will be a much closer link between study and production. In the scientific field it will probably result in alternating the student's activities between classroom and factory. This is, of course, similar to our own sandwich courses which have yielded very good results. Secondly, efforts will be made to shorten the present course of study which is based on the Soviet system. The Chinese are confident, from the experience gained in the past years, that their courses can be shortened by more intensive work without degrading the syllabus. Finally, more attention is to be paid to ability than memory. All university examinations are to be of the open book type, but the questions asked will be much harder than hitherto. All these seem to be very reasonable proposals designed to educate fairly rapidly a large number of competent scientists and technologists.

There is a curious tendency in Western countries to underrate the scientific and technological potential of the communist states. This may be largely because of the preoccupation of the daily press with ideological issues. It has caught the West unprepared when the sputniks went up after having been told that Russian science was relying largely on spying. It seems that we may be heading for a similar situation with regard to China when we are inundated by doubtful reports of internal unrest and impending civil war at a time when that country's scientific and technological potential is rising at this high rate.

# Principles of Classification and Nomenclature of Viruses

by  
ANDRE LWOFF

Service de Physiologie Microbienne,  
Institut Pasteur

Gibbs, Harrison, Watson and Wildy criticized the use of a binominal nomenclature for viruses (*Nature*, 209, 450; 1966) because, they said, equal weight cannot be given to all characters according to genuine Adansonian principles. Dr. Lwoff denies that this is so, and argues in favour of a binominal nomenclature.

In July 1966, in Moscow, the International Committee for the Nomenclature of Viruses (ICNV) met for the first time. Their discussions revealed that a number of virologists seemed to be unaware of the principles and significance of classification and also of the use and usefulness of a binominal nomenclature. A few virologists made use of a binominal nomenclature without knowing it, but it was obvious that systematic and nomenclature were sometimes confused. For example, Gibbs, Harrison, Watson and Wildy (from now on G.H.W.W.) write: "The idea of a code has recently been considered both for viruses and bacteria". Lwoff, Horne and Tournier dealt with viruses<sup>1,2</sup>, but discussed only classification, and did not mention the nomenclature which G.H.W.W. were concerned with.

The time has come when a discussion of the principles of classification and of nomenclature would be useful for both medical and plant virologists.

Specific things must have specific names which designate a category. In order to be recognized and identified, the category to which a given name applies should be defined accurately. For a category to be defined criteria have to be selected. How should we deal with the definition and nomenclature of viral categories? A few viruses, although different, exhibit a certain number of common characters. These related viruses must be placed in groups named in such a way as to avoid confusion, disorder, and changes of nomenclature.

Since the time of Linnaeus binominal nomenclature has been used extensively. As I have said, some virologists seem to ignore binominal nomenclature and others use it unknowingly. For example, three types of poliovirus have been recognized: I, II and III. These types are related; they share a certain number of properties which transcend their differences. Because of these common properties virologists have decided to give them the common name, Poliovirus. In a binominal nomenclature poliovirus would be the genus and I, II, III the species. When we speak of Poliovirus I, II or III we make use of a binominal system.

To group species under a common generic name is an act of classification; it means that the common traits as well as the differences of the species have been recognized. In this respect, but in this respect only, binominal nomenclature cannot be separated from systematics.

At the congress in Moscow the species was defined as a collection of viruses with like characters, and the genus as a group of species showing certain common characters. Both the species and the genus have to be named, and this implies an acceptance of binominal nomenclature, which is, of course, essential if nomenclature is to express the affinities of the viral species. Furthermore, the ICNV decided that "an effort should be made towards a latinized binominal nomenclature" and has, already, adopted some rules for the latinization of names. That latinization is necessary in order to confer an international status to a nomenclature has long been recognized by zoologists, botanists and bacteriologists.

When speaking of the virus of smallpox we use common

language, which also applies to pox virus. But, if we speak of *Poxvirus variolae*, we have a latinized binominal nomenclature. When G.H.W.W. speak of "Herpes virus simplex" they are very close to the latinized binominal nomenclature, *Herpesvirus simplex*. Is this latinized binominal nomenclature really a catastrophe, as some virologists seem to think?

Among the active opponents to the binominal system are G.H.W.W., who object that "the latin binominal system is rigidly based on the characters chosen to determine the form of the hierarchy of taxa: divisions, order, families, etc. . . ." A taxon is a specific group of organisms, such as mammals, diptera, mycobacteria, and a category is a rank in a categorical hierarchy. Thus the divisions, orders and families to which G.H.W.W. are referring to as taxa are categories.

If the virus of variola major is named *Poxvirus variolae*, and if it is the type species of the genus *Poxvirus*, then the name *Poxvirus variolae* will not depend on the nature of the characters used in the definition of, for example, families, orders and classes. In this respect, binominal nomenclature is unrelated to the form and hierarchy of categories of higher rank. Whatever the hierarchy of characters selected for the definition of families, orders, and other categories the end result would be the same. The second objection of G.H.W.W. to binominal nomenclature is that if one of the characters should be found unsatisfactory, then the whole hierarchy might collapse and new names would have to be found. It will not be because somebody finds the criteria of a given classification of viruses unsatisfactory that the classification will collapse, for the names of the classes and orders are completely independent of the names of the families, genera and species. The final objection that viral nomenclature should be based on a general classification of viruses is incomprehensible. Giving a name to a species means that its discriminative characters have been recognized, and to unite species into a genus is to recognize their common characters. To name a species or a genus is an act of nomenclature, and to group species into a genus is an act of classification. Nomenclature is not, however, based on a "general" classification of viruses. The name *Herpesvirus simplex* will be the same whatever the general classification of viruses. The herpes simplex virus of G.H.W.W., in a latinized binominal nomenclature, would be *Herpesvirus simplex*. The two names have exactly the same content of information and one cannot be bad if the other is good.

Thus, while criticizing classification in general, G.H.W.W. have started to define groups and to propose names. The groups are defined by a series of signs. For example, *Herpes simplex virus* is:  $\frac{D}{2} \frac{74}{X} \frac{S}{S} \frac{V}{0}$ , where

*D* stands for DNA and 2 is the number of strands; 74 is the molecular weight of the DNA and *X* is the percentage of DNA; *S* is the spherical shape of the "particle" and the spherical shape of the nucleocapsid; *V* is the vertebrate (host) and 0 means no vector is known.

The authors call this formula a cryptogram. As they point out, the cryptogram is part of the name and "a name should be simple, easily understood and usable by people speaking different languages". Yet most of the signs of the cryptogram correspond to the first letter of English words. And sigla have been forbidden by the ICNV. I should like to be sure that virologists really prefer a cryptogram to a name. Names like Herpesvirus or Poxvirus or Myxovirus are really more easily memorized than a formula with eight terms, and furthermore, in the list given by G.H.W.W., different characters are designated by the same letter. This is not going to clarify anything. Finally, most alphabets have only twenty-five letters and we have to label sixty characters.

When defining categories, should all characters or a selected few be considered? G.H.W.W. state: "We can think of no satisfactory way of estimating the relative importance of different characters and therefore consider it essential to follow the principles of Adanson, who suggested that all known information should be used and that all characters should be considered equally important". Mayr<sup>4</sup>, however, said that Adanson did advocate the weighting of characters, a process which, Mayr says, is essential to numerical methods.

Why, then, do pheneticists insist on non-weighting? One of many answers is that they do not know how to weight or that they do not like doing it. The other is that the programming of information fed to a computer is easier if all the characters have equal weight, that is the same information content.

G.H.W.W. consider that classification of viruses on Adansonian principles is now possible with the help of a computer. This might be true if genuine Adansonian principles are put to work and not G.H.W.W.'s misinterpretation. The question immediately arises: where does the computer lead? Sokal and Sneath, the main supporters of the computer, admit that "about the only thing it can do is the estimate of similarities between taxa. The rest of the taxonomic task needs the experience and the judgment of the specialist in the field."

The only operationally definable category is recognized to be the species, which can be pragmatically defined as a group of entities with identical characters, with the exception of phenotypic and genotypic alterations. It is the least arbitrary category. The genus is a group of different species. The family, a group of genera, the order, a group of families, and so on. All these categories are arbitrary, and even if the viral world was monophyletic, even if the complete phylogeny of viruses was known, a classification based on phylogeny would be unnatural and arbitrary, for many features of the viruses have certainly evolved independently. In order to classify, one must select characters, those characters which are fitted for a harmonious and logical system of order. Yet natural groups do exist in nature as a result of evolution. Viruses which show similarities have probably derived from a common ancestor. Because they share a certain number of characters they are united into the same category.

One category is necessarily different from another. Aristotle recognized that categories exist only by virtue of a definition, and, in order to define a category, discriminative characters have to be put to work. A category can be defined only by a character or a group of characters which are absent in other categories. If a family, for example, was defined by all the characters of one species there would be one family of each species. According to genuine Adansonian principles, a category should be defined by a minimum of characters. An array of other traits will serve to define the various different members of the category. Uniting a series of viruses under one name means that their useful discriminative characteristics have been recognized. The higher the rank of a category, the fewer must the characters be. If this elementary principle is ignored, no classification is possible.

Our system<sup>2</sup> makes use of four characters: the nature of the DNA or RNA; the symmetry of the nucleocapsid (helical or cubical); the nature of the nucleocapsid (naked or enveloped); the diameter of the nucleocapsid for virions with helical symmetry, or the number of capsomeres for virions with cubical symmetry. These four characters when used give categories which are recognized as valid by most virologists, for example, Poxviruses, Myxoviruses, Herpesviruses. So why add more characters to those four which are not only sufficient but also necessary? A system of classification which neglects the symmetry of the nucleocapsid would end up with categories including widely different unrelated species: viruses with a cubical and with a helical nucleocapsid would be in the same family.

If a computer had to deal with two viruses with fifty-nine like characters, the two viruses differing by the nature of the host: bacterium or vertebrate. In view of the fifty-nine like characters, the computer would place the two viruses in the same family, and would do exactly the same if the two viruses differed only by the nature of the genetic material or the symmetry of the nucleocapsid. The computer has no right to decide that a character should transcend another and has no way of selecting the characters according to their importance.

I suppose that most virologists will agree that two RNA viruses with cubical symmetry, a naked nucleocapsid and thirty-two capsomeres should belong to the same family, although one thrives in bacteria and the other in vertebrates. It is clear that the genetic material and the host should not have the same value so far as a classification is concerned.

Gibbs, Harrison, Watson and Wildy state that a classification of viruses should be based on at least sixty, equally weighted independent characters. When, however, they tried to define viral "groups", they selected eight characters.

For obvious reasons, practice has been different from theory, but either the theory or the practice should have led to a classification. Universally accepted, viral groups should have been "rediscovered", but this was not the case. Even the revised and amended principles have failed. A classification should be based on a minimal number of characters, rationally selected for their discriminative value. What virologists need is a real classification—and not unapplicable principles.

According to G.H.W.W., viruses cannot be classified objectively and rationally, but this should be possible soon. They consider that the existing classifications are irrational and subjective, but my colleagues have started naming "groups". It is recognized that the coining and application of any collective or generic term is an act of classification. Thus, when G.H.W.W. select characters, define and name groups, they are on dangerous ground; they are classifying, without knowing it.

A selection of characters is necessarily arbitrary, and it has the same degree of arbitrariness whoever makes the selection. The rationality of the selection should be judged objectively by asserting the usefulness of the characters for the classification.

The reader might ask why we want a classification. A classification is useful because it starts discussions, has a heuristic value, allows predictions, is useful for teaching purposes, and allows related viruses to be united into one and the same category. A negative attitude leading to an absence of classification has no value.

# Oxygen Isotope Analyses and Pleistocene Temperatures Re-assessed

by

NICHOLAS SHACKLETON

Sub-department of Quaternary Research,  
University of Cambridge

Oxygen isotope analyses of foraminiferal tests in deep-sea cores have been interpreted as showing that the temperature of seawater in the Caribbean and equatorial Atlantic varied by as much as 6° C during glacial cycles. This evidence has now been reinterpreted, and changes in oxygen isotope composition are now said to correspond with the extraction of large amounts of water from the oceans during glacial periods and the recirculation of this water during periods when glaciers were at their present levels.

THE method whereby palaeotemperatures are obtained by determining the oxygen isotope composition of carbonate fossils is now well known<sup>1-3</sup>. In recent years Emiliani has used this technique to elucidate the climatic record of the Pleistocene. To do this, he has made many hundreds of oxygen isotope analyses of the tests of planktonic foraminifera, taken from deep sea cores. Typically rather smooth curves representing the change in isotopic composition with depth in the cores (that is, with time) are obtained; the wavelength of the oscillations is very roughly 40,000 years, and the amplitude is about 1.65 parts per thousand in the Caribbean and the Equatorial Atlantic<sup>4</sup>. On the assumption that the isotopic composition of the oceans may have changed by about 0.5 parts per thousand, these measurements are interpreted as showing that the surface temperature of the Caribbean Sea and the Equatorial Atlantic fluctuated by about 6° C during the glacial-interglacial cycles.

From the beginning the results showed a satisfactory measure of agreement between the climatic record which Emiliani thus obtained, and the climatic record inferred by micropalaeontologists investigating faunal changes represented in the same deep-sea cores<sup>5,6</sup>. More recently a very detailed faunal analysis of a single core<sup>7</sup> has provided a climatic record which is almost identical with that obtained by Emiliani<sup>4</sup>.

Despite this striking agreement, many workers have doubted the validity of Emiliani's work<sup>8,9</sup> on the grounds that, although Emiliani has made allowance for the changing isotopic composition of the oceans during the waxing and waning of the continental ice sheets, his correction factor is not altogether well founded. This change in ocean isotopic composition is due to the fact that the isotopic composition of atmospheric precipitation, and hence that of a continental ice sheet, is different from that of the ocean; to give an extreme example, the isotopic composition of snow accumulating near the Pole of Inaccessibility in Antarctica is some 60 parts per thousand deficient in oxygen-18 compared with ocean water<sup>10</sup>. The factors governing the isotopic composition of atmospheric precipitation are well known<sup>11</sup>, and the likely average isotopic composition of a Pleistocene ice sheet can be estimated from information regarding its location, thickness and surface temperature distribution. Olafsson<sup>9</sup> has made such an estimate for the larger Pleistocene ice sheets, making an essentially two-dimensional approximation; that is, he assumes that the average isotopic composition taken over the surface of an ice sheet is a good approximation to its three-dimensional average. Having made this calculation, Olafsson suggests that the entire record of isotopic change recorded by planktonic foraminifera may be ascribed to changes in the isotopic composition of the oceans, after abstraction to the ice fields of about 2.5 per cent of the water now present in the oceans.

I have recently recalculated this effect, taking into account the flow of ice in three dimensions. This is quite

straightforward because the gross features of ice flow in a glacier are well known<sup>12</sup>. Even without assuming any decrease in air temperature during glacial stages, this calculation yields a result close to that obtained by Olafsson. (His calculation was criticized by Emiliani<sup>13</sup> because of the arbitrary nature of the air temperatures which he assumed.)

If such large changes in ocean isotopic composition have taken place, analyses of benthonic foraminifera, living in an environment of rather constant temperature, should yield exactly the same record as do analyses of planktonic foraminifera. I have analysed a selection of benthonic foraminifera from Lamont core A 179-4. Planktonic foraminifera from this core were analysed isotopically by Emiliani<sup>14</sup> and faunally by Ericson and Wollin<sup>5,6</sup>. The core was taken in the Caribbean Sea, south-east of Jamaica (16° 36' N., 74° 48' W., 2,965 m depth) and was described by Ericson and Wollin<sup>5</sup>. The samples analysed cover the last two "glacial" stages, and the intervening "interglacial"<sup>14</sup>, or "interstadial"<sup>15</sup>.

In Fig. 1 the benthonic analyses are plotted against Emiliani's determinations for the planktonic species *Globigerinoides sacculifer* from the same levels. Numbers denote the depth of each sample in cm below the top of the core. Point O (circled) represents the calculated isotopic composition of benthonic foraminifera living today, assuming a temperature of 4° C (ref. 15) and an isotopic composition for the water of -0.2 parts per thousand (ref. 16).

Bottom water in the Caribbean is derived from the Atlantic, being selected from about the 1,700 m depth level by the sill in the Virgin Island Passage<sup>17</sup>. The temperature crudely represents the bulk temperature of Atlantic water<sup>18</sup>, and would be expected to change with time to a small extent compared with changes in surface temperature.

If the glacial-interglacial variation in ocean isotopic composition had been 0.5 parts per thousand (compare Emiliani<sup>4</sup>, page 120), points on Fig. 1 should lie on line A. Similarly, if the variation had been 1.0 or 1.5 parts per thousand, points should lie on line B or C respectively. If there were no systematic change in temperature with changing isotopic composition, the points should lie on line D.

The fact that the points lie closest to line D shows that changing ocean isotopic composition is certainly the primary cause of the isotopic changes observed in planktonic foraminifera. I believe that the deviations from line D in the present series of measurements are likely to have been caused by random errors in measurement and random uncertainties in sampling. The latter occur because the benthonic foraminifera analysed may not have lived at exactly the same time as the planktonic individuals analysed by Emiliani. It is known that bottom mixing takes place on the sea floor; Arrhenius<sup>19</sup> quotes a mean mixing depth of 3-5 cm. Emiliani's measurements represent the average isotopic composition of some 100 to

400 foraminifera, and should be relatively independent of uncertainty caused by this effect. On the other hand, the benthonic determinations are based on between 0.3 and 0.4 mg calcium carbonate<sup>20,21</sup>, which may be obtained from three to ten individual foraminifera, and may be subject to some uncertainty on this account. The extent of the uncertainty obviously depends on the rate of change of isotopic composition; at most levels a small mixing would scarcely affect the result obtained, but at a point such as the 10 cm level, just above the sediment representing the rapid melting of the last continental ice sheets, a small mixing uncertainty would produce a large isotopic uncertainty.

The measurements made by Emiliani<sup>14,22</sup> on benthonic foraminifera from core 234 may be plotted and interpreted in a similar fashion. Emiliani has previously had to invoke the presence of excess glacial meltwater in the bottom water in order to explain these measurements. The presence of excess meltwater in the surface water has also been deduced<sup>9</sup>.

Emiliani has refuted the possibility that large changes in ocean isotopic composition have taken place<sup>13</sup> by referring to his own measurements of the isotopic composition of benthonic foraminifera from the Pacific Ocean<sup>23</sup>. These analyses are supposed to show that the maximum glacial-interglacial change in ocean isotopic composition was only 0.5 parts per thousand. Unfortunately the samples were selected according to Arrhenius's interpretation of the cores concerned, and their detailed relation to climatic changes is, in fact, far from proved<sup>24</sup>.

Until recently, satisfactory climatic records had not been obtained from Pacific cores by faunal analysis, but work by Blackman and Somayajulu<sup>24</sup> shows that suitably chosen cores display faunal changes of the same order as those observed in the Atlantic; these changes are presumed to have occurred synchronously in the two oceans. If this was the case, samples of benthonic foraminifera from the cores investigated by these workers, selected on the assumption that the faunal changes are indeed synchronous, should show the same change in isotopic composition as has been shown to have taken place in the Atlantic. I have analysed two samples from core DWBG 114 (taken at 18° 20' S., 79° 21' W., in a depth of 2,300 m), taken from 3-6 cm and from 15-17 cm (ref. 25). They

were selected to bracket the most recent transition from high latitude fauna to equatorial fauna; this should be the best period over which to test whether or not a significant change in isotopic composition took place in the Pacific, because we can feel very confident in correlating it with the similar transition in the Atlantic.

The results are given in Table 1. At present, the bottom temperature is about 1.5° C (ref. 26) and the bottom water has an isotopic composition near -0.17 parts per thousand (ref. 27), so that benthonic foraminifera living today will have an isotopic composition of about +3.8 parts per thousand; it appears that the large *Pyrgo* fragment which made up the bulk of sample 1 must be derived from a few cm lower, or elsewhere. Ignoring this measurement, the average for the 3-6 cm level is +3.7 parts per thousand, while the average for the 15-17 cm level is +5.1 parts per thousand, giving a difference of about 1.4 parts per thousand.

Table 1. ANALYSES OF BENTHONIC FORAMINIFERA FROM PACIFIC CORE DWBG 114

No.	Depth	Description	$\delta^{18}O$ (parts per thousand)
1	3-6	Large corroded <i>Pyrgo</i> fragment, and a few smaller fragments of <i>Pyrgo</i> sp.	+5.02
2	"	Several <i>Planulina</i> sp.	+3.57
3	"	Three <i>Orbulina</i> sp.	+3.82
4	"	Mixture of small benthonic spp. (no <i>Miliolidae</i> )	+3.73
5	15-17	Several <i>Uvulgerina</i> sp.	+5.03
6	"	Several small individuals <i>Pyrgo</i> spp., and fragments	+5.18

Emiliani has made one pair of analyses of benthonic foraminifera bracketing this short period; they are from a mixture of levels 43.5 and 53.5 cm in core 234, and from 2-3 cm in the pilot core 234.1A (ref. 22) (taken in the Eastern Equatorial Atlantic), and the isotopic difference is 1.61 parts per thousand.

We therefore have clear evidence that Atlantic and Caribbean surface waters, Atlantic bottom water, Pacific bottom water, and Atlantic deep water as represented by Caribbean bottom water, all registered a glacial-interglacial change in isotopic composition of about 1.4-1.6 parts per thousand, as predicted by realistic calculations.

It may still appear that this body of information could be incorporated into an explanation in terms of a pattern of temperature change. Here there are two restrictions. First, the change in isotopic composition is clearly required by calculations based on the fact that ice is known to have built up on the continents during certain stages of the Pleistocene. Second, in the circulating body of the oceans, we cannot postulate any reduction in the temperature at the heat sink in the system, because it is already near freezing point; this means that it is very difficult to postulate a large reduction in temperature in ocean bottom water, only two or three degrees higher than freezing at present, unless it is caused by an enormous drop in the heat put into the system. If this had been the case, surface temperatures would clearly have had to fall enormously. The isotopic evidence does not suggest any greater change at the surface than in the coldest depths. As regards changes in surface temperature of the order of a degree or so, this work only shows that there is no reason to restrict hypotheses to patterns of temperature change in which temperatures at the ocean surface drop in proportion to the extent of glaciation.

It was pointed out by Broecker<sup>28</sup> that the well documented movements in marine planktonic faunal provinces during the Upper Pleistocene could have been caused by changes in salinity rather than by changes in temperature. The evidence that has been presented shows that this was probably the case. An interesting consequence of this conclusion is that all the evidence which was previously interpreted as suggesting a rapid amelioration in climate close to 11,000 years ago, obtained from the investigation of deep-sea cores<sup>29</sup>, must now be interpreted as demonstrating the rapid melting of continental ice sheets at

Fig. 1. Oxygen isotopic composition of benthonic foraminifera from Lamont core A 179-1, plotted against oxygen isotopic composition of the planktonic species *Globigerinoides sacculifer* (Brady) as determined by Emiliani<sup>14</sup>. All analyses are expressed as deviations in parts per thousand (‰) from the PDB standard<sup>3</sup>. Analytical precision is  $\pm 0.20$ ‰ (2σ) for benthonic analyses and  $\pm 0.20$ ‰ (2σ) for Emiliani's measurements. One analysis (250 cm, +3.55‰) is of part of a benthonic echinoid.

this time. This is in good agreement with the terrestrial evidence.

An inspection of the detailed record which Emiliani obtained from core 179-4 (ref. 30) in the light of the present work reveals an apparent paradox. If the curve representing variation in the isotopic composition of the planktonic species *Globigerinoides rubra* and *G. sacculifer* must be interpreted entirely in terms of changes in the isotopic composition of the water, taking place through the whole column of water, then the species *Globorotalia menardii*, which registers a smaller glacial-interglacial range in isotopic composition than actually occurred in the water, must have lived in warmer water during the glacial periods than during the interglacials.

Closer examination shows that this is only to be expected on the basis of the evidence available. Emiliani<sup>31</sup> showed that the depth habitat of this species, as revealed by the isotopic temperature which it records, is determined by water density. Hence, as during a glacial period the water density increased with increasing salinity, the population of this species would need to migrate upwards to warmer levels in order to inhabit water of the preferred density.

Although it has generally been assumed that the temperature changes recorded in deep-sea cores were synchronous with the principal glacial episodes in the Northern hemisphere, this could only be proved for those glacial episodes which can be dated radiometrically. On the other hand, if the faunal and isotopic changes which have been observed are the result of the extraction of large quantities of water from the oceans and their storage in the form of ice, their relation to glacial events is unquestionable. It is simply necessary that every faunal or isotopic curve be re-read, taking "cold" to mean "extensive continental glaciation" and "warm" to mean "glaciers reduced to their present level".

In conclusion, it should therefore be emphasized that the time sequence which Emiliani<sup>4</sup> has been able to obtain by the analysis and correlation of many deep-sea cores remains of inestimable value; indeed, its value is in a sense enhanced by the certainty that it is a time-sequence for terrestrial glacial events, rather than oceanographic events. His work remains a uniquely valuable contribution to geology and equally to archaeology.

I thank Dr David Ericson, of the Lamont Geological Observatory, Palisades, New York, and Dr W. R. Riedel, of the Scripps Institution of Oceanography, La Jolla, California, for sending samples of cores A 179-4 and DWBG 114 respectively. Special thanks are due to the latter for sending the critical samples by return of post.

The mass spectrometer on which the measurements were made was purchased by means of a grant from the Department of Scientific and Industrial Research.

Among numerous individuals in many disciplines in Cambridge who have contributed to this piece of research through informal discussion, I should particularly like to thank Professor H. Godwin for his long-term encouragement, and Dr G. de Q. Robin of the Scott Polar Research Institute, Dr B. M. Funnell of the Sedgwick Museum and Dr R. G. West of the Sub-department of Quaternary Research for important stimulation in the final formulation of my conclusions. For advice and encouragement of a more practical nature, I am grateful to my colleagues in the Radiocarbon Dating Laboratory, Cambridge.

## An Antigenic Site of Sperm Whale Myoglobin

by  
M. J. CRUMPTON\*

Department of Immunology,  
St. Mary's Hospital Medical School,  
London

Part of the antigenic activity of sperm whale myoglobin is known to reside in the C-terminal region. A more detailed investigation shows that the C-terminal antigenic site of the molecule corresponds to the C-terminal hexapeptide which includes the corner between a helical segment and a non-helical segment of myoglobin.

PREVIOUS attempts to define the structural features of the antigenic sites of sperm whale myoglobin showed that the C-terminal heptapeptide of myoglobin partially inhibited the precipitation of metmyoglobin (MetMb) and apomyo-

globin (ApoMb) by certain antisera to MetMb<sup>1,2</sup>. The results suggested that the heptapeptide represented at least a significant portion of one of the antigenic sites of sperm whale myoglobin. An attempt has been made to delineate more closely the structure of the C-terminal antigenic site by comparing the inhibitory activities of a

\* Present address: National Institute for Medical Research, London.

Fig. 3. Inhibition of precipitation of 20.2 µg of ApoMb with 0.9 ml. of antiserum WD by increasing amounts (dissolved in 0.2 ml.) of peptides D2 (○), D2a (△), 1T2 (□), D3 (●), D1b (▲) and 1T1 (◇), and by peptide D2 which had been incubated at 37° C for 3 h with 5 per cent by weight of nagarse (×). The washed precipitates were dissolved in 0.5 ml. of 0.1 normal sodium hydroxide and the extinctions of solutions measured at 290 mµ; the decrease in extinction due to the inhibitor was expressed as a percentage of the extinction obtained in the absence of inhibitor ( $E_{290}^{1\text{ cm}} = 0.545$ ).

measuring inhibitory activities of some of the chymotryptic and tryptic fragments.

Peptides D3, D1b, D2, D2a, 1T1 and 1T2 (0.4 to 0.8 µmole) caused not more than 2 per cent inhibition of precipitation of ApoMb by antisera WM and WK. The experimental error of the inhibition test was equivalent to about 2 per cent inhibition, so that these peptides were probably inactive under the conditions used. In contrast, the precipitation of ApoMb by antiserum WD was inhibited by peptides D2, D2a and 1T2. The inhibitory activities of the peptides with antiserum WD are summarized in Fig. 3 and Table 2. The results indicated that peptides D3, D1b and 1T1 were probably inactive. On the other hand, it can be seen (Fig. 3, Table 2) that the C-terminal hepta- and hexa-peptides (D2 and 1T2 respectively) had similar inhibitory activities, which were less than that of peptide 1 (Table 1), and that the inhibitory activity of a pentapeptide (D2a) included in D2 was less than that of D2. It was concluded that peptides D2 and 1T2 represent at least a portion of either the antigenic site or one of the sites of peptide 1. The results also suggest that, whereas the C-terminal Gly and/or Gln residues contribute to the inhibitory activity of D2 and 1T2, the N-terminal Lys residue of D2 makes no significant contribution to the activity of D2. The activity of peptide D2 was destroyed almost completely by digestion with nagarse (Fig. 3). High-voltage electrophoresis at pH 3.5 of the nagarse digest, and elution and analysis of the peptides, revealed the presence of 10 per cent of undigested D2, 80 per cent of Lys-Glu-Leu and Gly-Tyr-Gln-Gly, and 10 per cent of Lys-Glu-Leu-Gly-Tyr and Gln-Gly. These results suggest that Lys-Glu-Leu and Gly-Tyr-Gln-Gly are not inhibitory and that the sequence Leu-Gly formed a part of the C-terminal antigenic site. Results closely similar to those reported for peptide D2 were obtained earlier using a different anti-MetMb serum (see Fig. 8)<sup>1</sup>.

The antigenic sites of myoglobin would be expected to be composed of amino-acid residues whose side-chains are exposed on the surface of the molecule. Although the N-terminal Lys of the C-terminal heptapeptide (D2) is exposed<sup>4</sup>, it does not form a significant part of the anti-

genic site detected by antiserum WD. As a result, this site may not be larger than the C-terminal hexapeptide (1T2). Antigenic sites composed of five to six residues have been reported for synthetic polypeptidyl proteins<sup>10</sup> and the dimensions of the C-terminal hexapeptide in native myoglobin (15 Å × 9 Å × 11 Å) are similar to those deduced for the combining-site of antibodies to dextran (34 Å × 12 Å × 8 Å)<sup>11</sup>. It is not known whether all the amino-acid residues of the hexapeptide contribute equally to the inhibitory activity, but the sequence Leu-Gly was essential and the C-terminal Gly and/or Gln made a contribution. In contrast, it has been reported<sup>7</sup> that the C-terminal dipeptide of myoglobin is not an essential part of an antigenic site of the native protein. This disagreement may be due to the use of different antisera which contained antibodies with different specificities. The C-terminal hexapeptide gave a maximum inhibition of about 11 per cent with antiserum WD, whereas the C-terminal 22-amino-acid peptide (1) gave 30 per cent. Consequently if the hexapeptide represents a complete site, peptide 1 must contain at least two sites. The molar ratio of peptide 1 to antigen for half the maximum inhibition (2) was much smaller than that of the hexapeptide (150). This difference of 75 times in inhibitory capacity suggests, in contrast with the view given earlier, that the hexapeptide forms only a part of the C-terminal antigenic site of myoglobin<sup>12</sup>. Comparisons of the inhibitory activities of peptides 42 and 44 of myoglobin<sup>1</sup>, and of peptides 8 and 8 (-5) of tobacco mosaic virus protein<sup>13</sup>, indicate, however, that the inhibitory capacity of a peptide may depend on amino-acids which are not included in the antigenic site. In this case, the inhibitory capacity is probably a measure of how closely the conformation of the site in the peptide approximates to that in the native protein. If the conformation of the hexapeptide when part of peptide 1 is more complementary to that of the antibody combining-site than the conformation of the free hexapeptide, then the results given do not disprove the suggestion that the C-terminal hexapeptide of myoglobin represents an antigenic site of the native protein.

Examination of the space-filling myoglobin model<sup>4</sup> reveals that the antigenic site(s) of peptide 1 could be formed from the amino-acid residues H8, 9, 12, 13, 15, 16, 17, 19, 20, 21, 23 and 24, and HO1-5 (Fig. 1), because only these residues or portions of these residues are exposed on the surface of myoglobin. In all probability, the C-terminal antigenic site includes the corner between the H-helix and the HO non-helical segment, in which case it probably comprises two faces at right-angles to each other. This site could include portions of the side-chains of all the amino-acid residues of the C-terminal hexapeptide and of the peptide bonds between residues HO3-2, HO2-1 and HO1-H24. So far as the model is concerned, there appears to be no obvious reason why the ε-amino group of Lys H23 does not form a part of this antigenic site; however, the exact positions of the side-chains of residues HO3, HO4 and H23 relative to each other are not known. In addition, the ε-amino group of Lys H21 would be expected to form a part of the same site, which suggests that the complete site may be larger than the C-terminal hexapeptide.

A comparison of the results obtained with different antisera reveals that the inhibitory activities of the peptides depend on the antiserum used. This variation is to be expected because different antisera may contain antibodies against different sites, and the antibodies to any one site may differ in the sizes of their combining-sites and in their affinities<sup>14,15</sup>. Because the fragments of peptide 1 that inhibited antiserum WD did not inhibit antisera WK and WM, the antigenic site(s) of peptide 1 relative to WK and WM may be larger or occupy a different position from that detected by WD. Alternatively, if the strength of binding of the fragments by the antibodies of antisera WK and WM is very much less than that of the antigen,

Table 2. MAXIMUM INHIBITION OF PRECIPITATION OF ApoMb WITH ANTISERUM WD BY PEPTIDES D2, 1T2 AND D2a, AND THE MOLAR RATIO OF PEPTIDE TO ANTIGEN FOR HALF THE MAXIMUM INHIBITION

Peptide	Maximum inhibition (%)	Peptide : ApoMb molar ratio for 50% of maximum inhibition
D2	11	150
1T2	10-11	150
D2a	>4	—

the fragments would appear to be inactive in the competitive inhibition test.

To sum up, the results indicate that the C-terminal 22-amino-acid peptide of sperm whale myoglobin, which is predominantly helical in the native protein, contains at least one of the antigenic sites of myoglobin. The C-terminal hepta- and hexa-peptides were also immunologically active, but they were less active than the 22-amino-acid peptide. As the C-terminal hepta- and hexa-peptides had similar inhibitory activities, the N-terminal lysine residue of the heptapeptide probably did not form part of the C-terminal antigenic site of myoglobin. It was, however, not clear whether the C-terminal hexapeptide represented a complete site or part of a site. Evidence was obtained that one or both of the C-terminal amino-acid residues and the leucylglycyl sequence of the hexapeptide were included in the C-terminal antigenic site of myoglobin. A pentapeptide, which was part of the C-terminal heptapeptide and which was less active than the heptapeptide, was the smallest inhibitory fragment isolated.

I thank Dr H. C. Watson for discussions on the structure of myoglobin, Professor R. R. Porter for his encouragement and Mr P. Revel for the amino-acid analyses. The

technical assistance of Mr P. B. Gillett is gratefully acknowledged. This investigation was supported by grants from the US National Science Foundation, the US Public Health Service, the Wellcome Trust and the Medical Research Council.

## Repopulation of Colony-forming Units in Mice

by

GERALD E. HANKS

Department of Radiology,  
Stanford University School of Medicine,  
Stanford, California

E. JOHN AINSWORTH

US Naval Radiological Defense Laboratory,  
San Francisco, California

Colony-forming unit repopulation has been studied in the mouse and compared with split dose total body radiosensitivity. This study indicates that post-irradiation changes in CFU do not correlate with changes in total body radiosensitivity.

When mice are exposed to X- or  $\gamma$ -radiation in semi-lethal doses, there is injury to the bone marrow with a marked decrease in the numbers of leucocytes and other cellular elements in the peripheral blood. The pancytopenia is ultimately attributed to radiation injury to the haematopoietic stem cell, that is, the killing of stem cells. The reaction of the animal to mid-lethal exposure—whether it survives or succumbs—is influenced by the surviving number of stem cells and the rate at which stem cells and their progeny proliferate and repopulate the haematopoietic system<sup>1</sup>.

Repopulation of a cell population from radiation injury seems to be divided into at least two phases: the first 24–48 h during which cellular or molecular repair of sub-lethal injury occurs, and then the proliferation of the surviving cells. These recuperative processes occur in irradiated cells cultured *in vitro*<sup>2–4</sup> and they may also occur in haematopoietic stem cells irradiated *in vivo*<sup>5,6</sup>.

There are now methods for determining the numbers of bone marrow or spleen cells which, after transplantation, can proliferate and form nodules or colonies in the spleens of supra-lethally irradiated recipient mice<sup>7,8</sup>. These colony-forming units (CFU) are thought to be haematopoietic stem cells although this has not been conclusively demonstrated<sup>1</sup>. If the size of the haematopoietic stem cell population is important in determining the radiosensitivity of an animal after sub-lethal irradiation, then the extent of stem cell proliferation after an initial exposure might be expected to correlate with, or even predict, the sensi-

tivity to a second radiation exposure. If the CFU is the stem cell or is indicative of the stem cell population, estimation of the number of CFU present after an initial exposure should at least qualitatively predict the sensitivity of the animal to a second radiation exposure.

An earlier report dealt with the extent to which the numbers of CFU in the marrow or the numbers of endogenous CFU in the spleens of mice could be correlated with the radiation protection produced by bacterial endotoxin<sup>9</sup>. Those data showed that in many respects the numbers of CFU did qualitatively correlate with the extent of radiation protection. By varying the time of endotoxin injection relative to irradiation, a procedure which influences both the extent of protection and the number of endogenous CFU, it was shown that radiation protection and the content of CFU in the spleen varied independently, and Smith *et al.* have reported similar findings<sup>10</sup>.

We have quantitatively transplanted bone marrow from sub-lethally irradiated donors to investigate the changes in the femoral CFU population after sub-lethal X-irradiation in mice treated with endotoxin and in control mice. We obtained values for the  $LD_{50}$  at various times where differences in CFU content predict differences in  $LD_{50}$  between the treated and control groups.

Female LAF1 mice between 3 and 4 months old were used. They were placed in 'Lucite' tubes which were placed on a rotary turntable for whole body irradiation by 250 kVp X-rays. The target skin distance was 40 in.; half value layer was 1.49 mm of copper and the dose rate

was 28–30 r./min. Endotoxin used in these experiments was 'Piromen', a highly purified *Pseudomonas* polysaccharide. In all experiments a dose of 50  $\mu$ g was given intravenously 24 h before irradiation in 0.05 ml.

Bone marrow was obtained as previously described<sup>8</sup>. The preparations were counted and appropriate dilutions were injected into supralethally irradiated (800 r.) recipients to determine CFU/10<sup>5</sup> cells. The irradiated recipients were housed singly as previously described<sup>8</sup>, and their spleens were removed 8 days after injection. Nodules greater than 0.24 mm were counted with the aid of a dissecting microscope, and from these data total nucleated cells, total femur CFU content and CFU/10<sup>5</sup> nucleated cells were determined.

Two groups of mice were used for single dose determinations of LD<sub>50/30</sub>. One group of mice received 50  $\mu$ g of endotoxin intravenously 24 h before irradiation; the other served as non-injected controls. Survival was recorded for 30 days. Median lethal doses (LD<sub>50/30</sub>) and other statistics were computed by methods previously described<sup>8</sup>.

Recovery from the initial radiation injury was investigated by the classical split-dose technique. Groups of control and treated mice received an initial or conditioning exposure of 450 r. (~ two-thirds of the control LD<sub>50/30</sub>). These animals were then divided into several groups and were re-exposed 5 or 14 days after the conditioning exposure to determine the LD<sub>50</sub>. The difference between the single exposure LD<sub>50</sub> and the redetermined LD<sub>50</sub> represents an estimate of the amount of injury remaining from the conditioning exposure at the time tested.

The bone marrow cellularity, the total CFU content of each femur, and the CFU content/10<sup>5</sup> nucleated cells were measured before and at various times after 450 r. These measurements were made in both treated (24 h before 450 r.) and control mice at the various times. Fig. 1 shows the changes in nucleated cell content and total CFU content of the femurs of treated and control mice. The nadir in nucleated cell count occurred at 3 days with the mice treated with endotoxin showing slightly less depression than the controls. Between 4 and 7 days the nucleated cell counts in the treated animals were rather larger than

Fig. 1. Time-dependent changes in the numbers of nucleated cells and colony-forming units in the femur of control mice or mice treated with endotoxin.

Nucleated cells 100 per cent =  $1.53 \times 10^7$  CFU 100 per cent = 4,750  
Controls —○— Endotoxin —△—

Fig. 2. Changes in femoral bone marrow CFU/10<sup>5</sup> cells after the irradiation of control mice and mice treated with endotoxin (450 r.). —○—, endotoxin; —△—, controls.

in the controls, and at 11 days the cellularity had returned to normal in both groups with some tendency to overshoot in the control animals. The femurs of mice treated with endotoxin contained about 70 per cent more CFU before exposure than did the controls. After the initial decrease in CFU the treated animals seemed to begin proliferation of CFU between 24 and 48 h after irradiation, while in control mice proliferation began after 48–72 h. The CFU content remained greater between days 1 and 7 in the treated animals, with a peak 5 days after irradiation in the endotoxin group. At that time the treated femurs contained ten times as many CFU as did control femurs (~2,000 versus ~200). After this there was a reduction in the total CFU content of the treated mice which was in contrast to the continuing proliferation in controls. The control mice later showed a 60 per cent overshoot at 14 days which was not seen in the endotoxin group, and both were near normal 23 days after irradiation.

Fig. 2 shows the changes in CFU/10<sup>5</sup> nucleated femur cells. This figure shows the relationship between the change in nucleated cell count and the change in CFU content. During any period when the CFU content increases proportionally with the nucleated cell content the curve would be flat, such as between 3 and 7 days in the controls and between 9 and 14 days in the mice treated with endotoxin. These treated mice had almost twice the concentration of CFU at the time of irradiation that the controls had, and after

4009 R349.

irradiation the treated animals showed an increase in concentrations of CRU 24 h before the controls showed any increase. There was a peak in the animals treated with endotoxin 5 days after irradiation, and this was succeeded by a secondary fall and a return to normal at 23 days. In controls, there was a rapid increase in concentration of CRU during days 2 and 3, followed by a plateau between days 3 and 7 at which time CRU content was about 30 per cent of the normal value. This was followed by a second increase to the normal range 14 days after irradiation.

Table 1. EFFECT OF ENDOTOXIN ON SINGLE AND SPLIT-DOSE  $LD_{50}$

Treatment	No. of mice	$LD_{50}$ (r.)
Single exposure		
Endotoxin*	79	924 (915-938)†
Controls	180	707 (691-723)
Split dose‡		
5 day endotoxin	148	696 (683-714)
Control	132	675 (651-710)
14 day endotoxin	184	731 (717-748)
Control	133	711 (697-728)

\* 50  $\mu$ g was given 24 h before irradiation.

† Brackets include 95 per cent confidence limits.

‡ Initial exposure 450 r.; 50  $\mu$ g of endotoxin was given before the initial exposure only.

Table 1 contains the single and split-dose  $LD_{50}$  determinations for treated and control mice. Twenty-four hours after treatment with endotoxin the single exposure  $LD_{50}$  was increased by 217 r. (924 r. versus 707 r.). The values of  $LD_{50}$  for treated and control mice were not different when tested 5 days or 14 days after 450 r. had been given.

In these experiments we have measured the changes in nucleated cell content and the CRU content in the femurs of sub-lethally irradiated mice. A comparison has been made between treated and untreated mice, with the object of evaluating certain aspects of haematopoietic recovery, and to attempt to relate recovery of the bone marrow CRU content to split-dose radiosensitivity.

The data show that endotoxin given 24 h before 450 r. increased the marrow CRU content at the time of irradiation without affecting marrow cellularity. This finding is in contrast to the findings of Smith *et al.*, who reported no increase in CRU content after treatment with an endotoxin derived from *S. typhosa*<sup>10</sup>. As expected, the post irradiation decrease in CRU was more rapid than the fall in marrow cellularity because the CRU assay is a viability assay. The fall in nucleated cell count is probably the combined result of reduced production, cell death, and loss of cells through maturation and release into the circulation. The extent to which release from the marrow influences the decrease in CRU content in either the treated or the control group is not known, although the units are normally released from the bone marrow at a constant rate, and endotoxins appear to increase this rate of release<sup>9,12,13</sup>.

The increase in femoral CRU content began about 24 h earlier in the animals treated with endotoxin than in the control animals, and in both groups the increase in the CRU preceded the increase in marrow cellularity by 1 or 2 days. During the first 5 days the rate of increase in CRU content may be greater in the treated than in the control animals, and this is also the case for marrow cellularity between days 3 and 7. Such an early increase in marrow cellularity in animals treated with endotoxin has been reported and these patterns of change in CRU during the first 5 days are similar to those observed in another strain of mice injected with endotoxin from *S. typhosa*<sup>11</sup>. It thus seems likely that the mice treated with endotoxin begin their post-irradiation proliferation earlier as a result of previous stimulation of the CRU compartment by the administration of endotoxin.

Between days 5 and 9 there was a marked decline in CRU content of the endotoxin-treated mice and a slight decrease in marrow cellularity. This decrease in CRU at 9 days is of considerable interest, for it suggests that the proliferative system producing CRU was exhausted by the "double" stimulation or responded to a feed-back inhibition.

At 11 and 14 days an "overshoot" in marrow cellularity was observed in both groups, and an overshoot in CRU was observed in the controls but not in the animals treated with endotoxin. During this time the CRU content in the treated animals was smaller than in the controls, as if the earlier more rapid production of CRU was at the expense of those present at 11 and 14 days.

Our data permit determination of the correlation of CRU content with split-dose radiosensitivity. If the CRU is the haematopoietic stem cell or if at any given time the CRU content is directly related to the size of the stem cell population, then animals with a greater CRU content would be expected to have a larger  $LD_{50}$ .

The present data concerning split-dose  $LD_{50}$  indicate that split-dose radiosensitivity and femoral CRU content vary independently. Five days after 450 r. had been given the  $LD_{50}$  of the animals treated with endotoxin was not significantly different from that of controls, in contrast to the 200 r. difference predicted by a ten-fold difference in the number of CRU with a  $D_{57}$  of about 90 r. At 14 days, the values for  $LD_{50}$  for the treated and control animals again were not different, although the CRU content was about three times greater in the control animals and would predict a 90 r. difference.

Five days after 450 r. had been given the CRU content was about 4 per cent of normal, while the redetermined  $LD_{50}$  indicates that there has been recuperation from 95 per cent of the initial injury (single dose  $LD_{50}$ —redetermined  $LD_{50}$ =residual injury, that is, 707 r.—675 r.=32 r. residual injury). In addition, 14 days after irradiation the bone marrow of the control animals contained about 50 per cent more CRU than before irradiation. This would predict their  $LD_{50}$  to be about 50 r. greater than that of untreated mice. This was not found, because the re-determined  $LD_{50}$  was the same as that of control mice.

The value and widespread application of the spleen CRU techniques for investigating the various radiobiological and physiological responses of this cell line are well established. A logical extension of these findings has been to equate the CRU with the bone marrow stem cell, or to assume that changes in the CRU closely reflect changes in stem cell populations. The present investigation indicates that with the methods now available, and the inherent problems in the methodology and interpretation, measurable changes in CRU content of the bone marrow do not correlate with variations in split-dose radiosensitivity, and therefore may not be closely reflecting changes in the stem cell population. The following are some of the factors which may be relevant: (a) The CRU may not be related closely enough to the "stem cell" to reflect accurately the changes in this cell population. (b) The bone marrow "stem cell" and CRU may be closely related or the same, but are not the chief factor in determining split-dose radiation sensitivity. (c) After an initial exposure the bone marrow stem cells of CRU may be particularly sensitive to trauma which could prevent accurate assessment of their total numbers by the commonly used transplantation techniques.

This work was supported by the US Bureau of Medicine and Surgery and the Defense Atomic Support Agency.

# Tissue Typing in Man

by

ARNOLD R. SANDERSON

McIndoe Research Unit,  
Blond Laboratories,  
Queen Victoria Hospital,  
East Grinstead, Sussex

Human lymphocytes which are essentially free from other cells have been prepared from peripheral blood. Storage for long periods at  $-196^{\circ}\text{C}$  is possible without serious loss in viability. Labelling with chromium-51 enables such cells to be used in a precise serological assay with human isoantisera and rabbit complement. The procedure may well prove useful in typing human tissues.

TRANSPLANTATION of tissues between individual members of an outbred species is, with limited exceptions, followed by rejection of the grafted material. This rejection is frequently accompanied by the appearance of humoral antibodies the specificities of which reflect the histocompatibility differences between graft donor and recipient.

Many *in vitro* assay systems are available for examining the antibodies and the iso-antigens which invoke their appearance. The majority of techniques, however, involve a subjective interpretation of results, principally that of a microscopic examination of a cell population (that is, antigen) which has been damaged or agglutinated by antiserum. The introduction of precision and reproducibility into such tests would be most useful.

The release of chromium-51 from labelled lymphocytes in the presence of specific isoantisera and complement has proved a valuable objective tool in several studies on isoimmunity in mice<sup>1-4</sup>. The availability of a similar test system for man would aid histocompatibility typing and elucidation of the chemical nature of the relevant antigenic specificities.

The principal difficulty lies in the requirement for a homogeneous cell suspension in the chromium-51 assay. Inhomogeneity would introduce such variable parameters as differential labelling, fragility and isoantigen content of the various cell types. In the past few years several communications have appeared<sup>5-7</sup> describing the preparation of lymphocytes from peripheral blood. The high purity of these preparations (frequently reported as more than 95 per cent) refers, however, to contamination with other leucocytes. This ignores any contribution made by erythrocytes, which may well comprise three-fourths of the final cell population.

This report deals with the preparation of lymphocytes virtually free from any contamination, and their use, either fresh or after storage at  $-196^{\circ}\text{C}$ , in a human isoimmune chromium-51 cytolytic assay.

**Preparation of lymphocytes.** Peripheral blood (10 ml.) is defibrinated using glass balls (3 mm diameter). After separation from the clot, the supernatant fluid is mixed with one-third its volume of a fresh, warm ( $37^{\circ}\text{C}$ ), 3 per cent solution of gelatine in saline<sup>8</sup>, and erythrocytes are allowed to sediment at room temperature for 20 min. The upper layer rich in leucocytes is removed, centrifuged at 300g for 10 min at room temperature, and the pellet is resuspended in 1 ml. of 25 per cent foetal calf serum in tissue culture fluid 199 (ref. 8). (This medium is used thereafter throughout the preparation.) To the suspension is added an appropriate amount of the IgG fraction of chicken anti-human erythrocyte serum. (The production of this antiserum and the rationale of its use are discussed later.) The erythrocytes agglutinate firmly and settle out within 20 min at  $37^{\circ}\text{C}$ . The supernatant suspension

of leucocytes is carefully removed with a Pasteur pipette. This suspension is then introduced to a column (1 cm  $\times$  10 cm) of polystyrene-divinyl benzene beads<sup>9</sup> prepared in phosphate-buffered saline, and maintained at  $37^{\circ}\text{C}$  by a water-circulating jacket. Cells are washed into the body of the column with medium, followed by incubation at  $37^{\circ}\text{C}$  for 15 min. Medium is then percolated through the column. Unadsorbed cells are rapidly displaced and easily observed in the eluate; collection is usually completed in about 4 ml. of fluid following their first appearance. Centrifugation at 300g for 5 min allows collection of all cells in the eluate and also serves to pack any eluted erythrocytes firmly at the bottom of the centrifuge tube. Gentle resuspension of the pellet in a small volume of medium invariably fails to disaggregate the erythrocyte button which is thereby easily removed. Table 1 summarizes results obtained from three typical preparations of lymphocytes. The method may be scaled up to process 250 ml. of peripheral blood without difficulty. The lymphocytes so obtained are adjusted to a concentration of  $250 \times 10^6/\text{ml}$ . and to the stirred suspension is added 0.5 volumes of 30 per cent dimethyl sulphoxide in medium. 15  $\mu\text{l}$ . volumes of the mixture are sealed in haematocrit tubes, cooled at  $1^{\circ}\text{C}/\text{min}$  to  $-30^{\circ}\text{C}$  (ref. 10) and then more rapidly to  $-196^{\circ}\text{C}$ , and stored in liquid nitrogen.

Table 1. PREPARATION OF LYMPHOCYTES FROM PERIPHERAL BLOOD

Donor *	Purification stage	Erythrocytes	Leucocytes	Lymphocytes
RoCh	Original blood	59,400 †	93	37
	Defibrinated blood	40,900	43	23
	Gelatine supernatant	98	31	10
	Column eluate	0.1	0.15	7.5
ArSe	Original blood	58,500	96	36
	Defibrinated blood	45,700	65	31
	Gelatine supernatant	82	23	8.5
	Column eluate	0.1	0.14	6.4
BaFo	Original blood	61,200	61	31
	Defibrinated blood	47,000	46	21
	Gelatine supernatant	97	23	9.0
	Column eluate	0.1	0.11	7.7

\* 10 ml. blood was drawn in each case.

† All values are  $\times 10^6$ , and refer to the total cells of each type stated.

The lymphocyte suspensions are more than 99 per cent viable after trypan blue staining, and transform into blast-like cells on culture with phytohaemagglutinin<sup>11</sup>. Rapidly thawed suspensions which have been maintained at  $-196^{\circ}\text{C}$  for 2 months are more than 85 per cent viable and transform in a manner identical with freshly prepared cells. Preparation time is about 2 h, but if freezing is desired, sealing and cooling occupy a further 2 h.

**Chicken anti-human erythrocyte serum.** Chickens (White Leghorns) are immunized by multiple intravenous injections at fortnightly intervals with a 25 per cent suspension of packed, washed, human erythrocytes in phosphate-buffered saline. Birds showing high agglutinin titres are

bled 2 weeks after the final injection, serum is prepared and the IgG fraction separated on 'Sephadex G-200'. Phosphate-buffered saline at five times physiological strength is used as eluent, because it was found that lower ionic concentrations produced poor and irreproducible results<sup>12</sup>. The fractions containing IgG are concentrated and titrated using  $100 \times 10^6$  human erythrocytes in a total volume of 0.5 ml. with an incubation time of 20 min at 37° C. A strong macroscopic agglutination is used as the endpoint. The results of this titration allow simple calculation of the appropriate dilution of antiserum to be used during lymphocyte preparation.

In preliminary experiments erythrocytes were preferentially lysed (15 min at room temperature) using rabbit anti-human erythrocyte serum and guinea-pig complement. Lymphocyte preparations so obtained appeared microscopically normal, and were not agglutinated. Nevertheless when these lymphocytes were labelled and suspended in rabbit complement or guinea-pig complement alone, for 1 h at 37° C, considerable lysis was observed. The samples of complements used had been absorbed with human cells and were known to be non-toxic under the conditions used. Small amounts of the rabbit anti-erythrocyte serum appear therefore to attach to lymphocytes, presumably because of cross-reacting specificities between them and erythrocytes. Such antibodies apparently sensitized the lymphocytes, and caused lysis in the presence of complement alone during the conditions subsequently used in the isoantiserum assay, namely, 1 h at 37° C.

The use of chicken antiserum overcomes this problem, by utilizing the known<sup>13</sup> inability of chicken antibodies to cause lysis with any species of complement except their own. Now the lymphocytes so obtained may have a little chicken antibody on their surface, but because they are ultimately suspended in rabbit complement, such antibody cannot cause lysis, and therefore any cytotoxicity observed must be the result of sensitivity to the isoantiserum under test.

The agglutinins occurring in the IgG portion of chicken anti-erythrocyte serum were selected rather than using the whole serum. The simple 'Sephadex G-200' separation obviates any potential dangers caused by the presence in whole serum not only of complement but also of IgM anti-erythrocyte cytotoxins of known high lytic efficiency (unpublished data). The separated IgG, on the other hand, did not lyse human erythrocytes in the presence of chicken complement, thereby confirming the usual<sup>14</sup> poor lytic efficiency of this type of antibody.

Finally, it should be added that human lymphocytes obtained using the IgG antibody were not agglutinated by 1:10 guinea-pig anti-chicken globulin serum. The titre of IgG anti-erythrocyte agglutinins was, however, augmented by a factor of ten by the same concentration of guinea-pig antiserum. It therefore seems that the amount of chicken antibodies present on the purified lymphocytes is either nil or very little.

**The isoantiserum cytotoxic assay.** The chromium-51 assay is essentially similar to that described earlier for mouse lymphocytes<sup>1</sup>. Labelled cells are added to dilutions of isoantiserum in complement and, after an appropriate incubation, lysis is arrested. Released isotope is determined in aliquots of supernatant after centrifugal removal of cells and debris. Control tubes of cells added to diluent alone, with or without incubation, and to complement alone, are always included. Details of modifications to the reported assay are dealt with below.

(a) **Suspension media.** Cells are labelled at 37° C for 3 h at a concentration of  $20 \times 10^6$ /ml. in 10 per cent foetal calf serum containing 5 mc. chromium-51/ml. Excess isotope is washed from the cells with veronal-buffered saline containing optimum amounts of calcium and magnesium for complement activity, and 0.1 per cent of gelatine. This medium is used as the routine diluent thereafter in the lytic assay.

(b) **Cell numbers.** 3,000 lymphocytes are used per assay tube, although this by no means represents a lower limit of cell numbers; as little as 250 cells have been used. Provided satisfactory defibrination can be achieved it is therefore possible to type patients from pin-prick blood samples, which should considerably widen the applicability of the technique. Human lymphocytes appear to absorb more chromium-51 per cell than mouse lymphocytes, where 100,000 are usually necessary to achieve similar label release. This is not only sparing of target cells but may result in greater sensitivity than is found in comparable cytotoxic assays, for example, trypan blue exclusion, where larger cell numbers are necessary.

(c) **Temperature.** Human cells again possess an advantage over mouse cells. For the latter it is necessary to incubate at room temperature in order that "background" controls, that is cells with diluent only, remained low. With human cells, however, such controls are only 2 per cent greater than unincubated values after 1 h at 37° C.

(d) **Complement.** Pooled rabbit serum is adsorbed three times for 10 min at 0° C with freshly washed, packed human erythrocytes, stored at -20° C in 1 ml. volumes, and used within 2 months of preparation. Human isoantisera titrated with rabbit complement are invariably found to give higher titres than with guinea-pig complement, provided the complement units present are identical for the two cases. Similar reports on the greater efficiency of rabbit over guinea-pig complement have been made previously<sup>15</sup>. An interesting finding, however, is that when the same batches of complement from these two species are titrated with identically sensitized target cells, guinea-pig titres are much higher than rabbit. It therefore seems that guinea-pig serum may have more units of complement/ml. than rabbit serum, but the former is of a lower lytic ability per unit.

(e) **Termination of lysis.** Lysis is terminated with ethylenediamine tetraacetic acid (EDTA) in saline, as previously described<sup>1</sup>, except that trypsin is incorporated to give a final concentration of 0.08 per cent in the cell suspension. Earlier work showed that not all incorporated isotope is released during lysis. The maximum release measured probably depends on the degree of damage inflicted, and where the relevant antigen density is low, such injury could be insufficient to allow all the labelled macromolecules to escape from cells within the lytic period. Trypsin overcomes this problem by causing complete disruption of any damaged cell: undamaged cells are not affected (compare ref. 16). A purified form of trypsin is used and, because the enzyme has no metal requirement for activity, it is unlikely that EDTA causes

Fig. 1. Isoimmune lysis of human lymphocytes. Abscissa: antiserum dilution. Ordinate: lysis (per cent). O, Reaction terminated with EDTA-saline; □, reaction terminated with EDTA-saline containing trypsin (final concentration 0.08 per cent).

Fig. 2. Isoumune lysis of fresh and stored human lymphocytes. Abscissa: antiserum dilution. Ordinate: lysis (per cent). O, Lymphocytes freshly prepared and labelled; □, lymphocytes labelled, stored for 24 h at 4° C and used; △, lymphocytes cooled to -196° C, stored 6 weeks, thawed, labelled and used.

any inhibition. Titrations for antisera remain unchanged, as an examination of Fig. 1 will show, while sensitivity, in terms of released chromium-51, is considerably increased. Furthermore, because trypsin causes complete isotope release on complete lysis, all isoantisera are strictly comparable. When EDTA alone is used to arrest lysis, particularly after using a polyspecific isoantiserum, a maximum of about 65 per cent of incorporated label is liberated, very similar to values obtained in mouse lymphocyte lysis. It seems highly likely, however, that isoantisera will be found where this figure is much lower, as was found in mouse.

A comparison of such maxima obtained within a given lytic period and for the same cell type but with different

antisera, may indeed reveal valuable information about the density of antigenic determinants on the target surface. For present purposes of a typing test, however, increased sensitivity is considered to be of greater importance, and a trypsin containing termination reagent is routinely used.

Results of the chromium-51 assay performed on fresh or frozen-stored cell suspensions are shown in Fig. 2, which suitably indicates the reproducibility of the system. Suspensions of stored cells do give a higher background liberation of isotope, seen in the control where reaction is terminated without incubation at 37° C. This background is, however, subtracted from all values before calculation of lysis in other tubes. When this "zero time" value is expressed as percentage of label present in cells, it closely approximates the percentage of cells stained by trypan blue.

I thank Dr J. R. Batchelor for supplies of human isoantiserum, Dr A. Szenberg for valuable advice and Dr H. Feistenstein for differential cell counting and microscopic assessment of lymphocyte transformation in tissue culture.

## New Semi-synthetic Penicillin active against *Pseudomonas pyocyanea*

by

P. ACRED

D. M. BROWN

E. T. KNUDSEN

G. N. ROLINSON

R. SUTHERLAND

Beecham Research Laboratories,  
Brockham Park,  
Betchworth, Surrey

Most of the semi-synthetic penicillins developed from 6-aminopenicillanic acid have little or no activity against *Pseudomonas pyocyanea*.  $\alpha$ -Carboxybenzylpenicillin (carbenicillin: BRL 2064), on the other hand, is active against these organisms and seems to be almost completely non-toxic to man.

DURING the preparation in these laboratories of many hundreds of semi-synthetic penicillins from 6-aminopenicillanic acid, activity against *Pseudomonas pyocyanea* (*Pseudomonas aeruginosa*) has been found only infrequently. This article describes investigations of the properties and pharmacology of one compound that has been selected for

clinical trial. The clinical results (to be reported elsewhere) have shown that carbenicillin has effective anti-*Pseudomonas* activity when given to human subjects by intramuscular or intravenous injection. As with most penicillins, carbenicillin is virtually non-toxic and has no local irritant effects.

## Chemistry

The introduction of ionized substituents into the side-chain of benzylpenicillin (I) is known to lead in some cases to enhanced activity against certain Gram-negative bacteria, as in ampicillin (II) which contains a basic  $\alpha$ -substituent. We now wish to report on an analogue with an acidic  $\alpha$ -substituent, namely  $\alpha$ -carboxybenzylpenicillin (III: carbenicillin).

I:  $R=H$  (benzylpenicillin)

II:  $R=NH_2$  (ampicillin)

III:  $R=CO_2H$  (carbenicillin)

Carbenicillin (which will shortly be available under the registered trademark of 'Pyopen' from Beecham Research Laboratories) is supplied as the disodium salt and contains 5-6 per cent water. It is a white powder which dissolves freely in cold water to give a solution with a pH between 6 and 8. Carbenicillin is only moderately stable to acid, the half life at 21° C and pH 2.0 being about 140 min and at 37° C and at pH 2.0 about 80 min.

On prolonged storage, carbenicillin may decompose to some extent into benzylpenicillin and carbon dioxide. The presence of benzylpenicillin can readily be detected by paper chromatography in butanol-ethanol-water followed by development on an agar plate seeded with *B. subtilis*. Carbenicillin gives a zone of inhibition of bacterial growth near the origin ( $R_f$  about 0.03) whereas benzylpenicillin has an  $R_f$  of about 0.4. The technique is sensitive because benzylpenicillin is considerably more active than carbenicillin against Gram-positive bacteria.

## Microbiology

The antibacterial spectrum of carbenicillin is shown in Table 1. Serial dilutions of the drug were prepared in agar in Petri dishes and the surface of the agar was inoculated using one drop of undiluted overnight broth cultures. The minimum inhibitory concentrations were read after incubation overnight at 37° C. In some respects the antibacterial spectrum of carbenicillin is similar to that of ampicillin. For example, carbenicillin shows significant activity against penicillin-sensitive staphylococci and the streptococci, although this is substantially lower than that of ampicillin or penicillin G. Also, carbenicillin is not stable to staphylococcal penicillinase and is relatively inactive against penicillin-resistant strains of staphylococci. Against *Haemophilus influenzae*, *Escherichia coli*, *Salmonella* species, *Shigella* species and *Proteus mirabilis*, carbenicillin shows a similar level of activity to that of ampicillin although, in general, the activity of carbeni-

cillin is somewhat lower. Like ampicillin, carbenicillin shows only a low level of activity against most strains of *Klebsiella aerogenes*. The spectrum of carbenicillin differs from that of ampicillin, however, with regard to *Pseudomonas pyocyanea* and certain *Proteus* species and carbenicillin is primarily interesting because it is active against these organisms.

**Activity against *Pseudomonas pyocyanea*.** Compared with the activity one is accustomed to see with most antibiotics of clinical value, the activity of carbenicillin against strains of *Ps. pyocyanea* is low. Not many antibiotics are effective against *Pseudomonas*, however, and in the case of those which are active there are certain problems of toxicity. Carbenicillin, on the other hand, is remarkably free from toxic effects and this allows a dosage to be used which can result in inhibitory concentrations being reached in the body even though these levels are comparatively high.

Table 2. ACTIVITY OF CARBENICILLIN AGAINST *Pseudomonas pyocyanea*  
Minimum inhibitory concentration\* ( $\mu$ g/ml.) and number of strains

No. of strains	250	125	50	25	12.5	5.0
74		6	50	15	3	

\* Determined by serial dilution of the drug in agar; inoculum one drop of overnight broth culture diluted 1/100.

Table 3. EFFECT OF CARBENICILLIN ON THE GROWTH OF A TYPICAL STRAIN OF *Ps. pyocyanea*

Inoculum	500	250	Carbenicillin ( $\mu$ g/ml.)	125	50	25	12.5	5.0	2.5
Undiluted (about $10^7$ cells)	growth barely discernible		sparse growth with some separate colonies		confluent growth				
Diluted 1/100 (about $10^4$ cells)	no growth				semi-confluent growth				

Serial dilutions of carbenicillin prepared in agar and the surface inoculated by flooding with overnight broth culture

The activity of carbenicillin against seventy-four strains of *Ps. pyocyanea* is shown in Table 2. All the strains were recent clinical isolates. It will be seen that a concentration of 50  $\mu$ g/ml. carbenicillin was required to inhibit the majority of the strains. Some strains were inhibited by 25  $\mu$ g/ml. but other strains were only inhibited with concentrations as high as 125  $\mu$ g/ml. Determination of the minimum inhibitory concentrations of carbenicillin is made difficult by the fact that typical strains of *Ps. pyocyanea* do not show a sharp end point when the inoculum is heavy (Table 3). When a heavy inoculum is used, that is, one comprising  $10^6$  or more cells, confluent growth occurs on agar containing concentrations of carbenicillin up to about 12.5  $\mu$ g/ml., and at this concentration of drug there is no evidence of any inhibitory effect. At a concentration of 25  $\mu$ g/ml. carbenicillin, however, growth is extremely scanty compared with the control and the inhibitory effect of the drug at this concentration is very marked, although growth is by no means completely inhibited. At concentrations of carbenicillin above 25  $\mu$ g/ml., growth is extremely meagre, taking the form of a very thin film which may only just be discernible on the surface of the agar. Consequently, if the criterion of the "minimum inhibitory concentration" (MIC) is one of absolute inhibition of any trace of growth, the MIC with a very heavy inoculum may well be as high as 250  $\mu$ g/ml. or more, as a result of the scanty growth which occurs at concentrations of carbenicillin of 25  $\mu$ g/ml. and greater. When a smaller inoculum is used in the sensitivity tests, a relatively sharp end point is obtained. With an inoculum of about  $10^4$  cells a normal, pigmented, semi-confluent growth is obtained on agar with concentrations of carbenicillin up to 12.5  $\mu$ g/ml., but at 25  $\mu$ g/ml. and over there is usually no growth at all.

As might be expected, this effect of inoculum size on the MIC of carbenicillin is also seen when the tests are carried out in liquid medium. With a heavy inoculum, growth appears normal with formation of pigment and pellicle up to a concentration of about 12.5  $\mu$ g/ml. carbeni-

Table 1. ANTIBACTERIAL SPECTRUM OF CARBENICILLIN

	Minimum inhibitory concentration ( $\mu$ g/ml.)*
<i>Escherichia coli</i>	5.0

\* Serial dilution in agar; inoculum, one drop of an overnight culture.

† Penicillinase-producing strain.

illin, but at 25  $\mu\text{g/ml}$ . there is no pellicle or pigment and growth is markedly diminished, although complete inhibition of growth may only be obtained with concentrations as high as 250  $\mu\text{g/ml}$ . With a smaller inoculum, a sharp end point is obtained and with most strains of *Pseudomonas* the MIC under these conditions is usually about 50  $\mu\text{g/ml}$ .

This effect of inoculum size on the MIC is outwardly similar to that seen with penicillin G and penicillinase-producing staphylococci. Carbenicillin, however, is itself highly stable to the penicillinase produced by typical strains of *Ps. pyocyanea* and the inoculum effect in this case is not due to destruction of drug, nor is the effect due to the growth of resistant mutants present in the original inoculum. When sensitivity tests are carried out on the growth which occurs in the presence of high concentrations of carbenicillin the result obtained is the same as that seen with the original culture, that is, marked suppression of growth at concentrations of 25  $\mu\text{g/ml}$ . and over, but with scanty growth nevertheless persisting up to a concentration as high as 250  $\mu\text{g/ml}$ . when the inoculum is heavy.

Carbenicillin is bactericidal and typical results with a strain of *Pseudomonas* are shown in Fig. 1. For the first 7 h a concentration of 50  $\mu\text{g/ml}$ . usually results in the killing of at least 99 per cent of the original inoculum, but some resumption of growth takes place thereafter which may even increase to a visible amount after 24 h. When this growth is used as inoculum in a repeat test, the same kill is again obtained over the first 7 h followed by a certain amount of growth. The reason for this bactericidal effect followed by growth is not known, but it does not seem to be due to the selection of resistant mutants present in the original inoculum.

**Activity against *E. coli* and *Proteus* species.** Table 4 shows the activity of carbenicillin and ampicillin against strains of *E. coli* and *Proteus* species. Against *E. coli*, carbenicillin shows activity equal to that of ampicillin when tests are carried out using dilutions of the drug in agar. An inoculum effect is also seen with *E. coli*, however, similar to that described with *Pseudomonas*. This effect is more marked with some strains of *E. coli* than others and it is also more pronounced when the tests are carried out in liquid medium. Consequently the results of sensitivity tests with *E. coli* carried out in broth frequently show carbenicillin to be markedly less active than ampicillin when the inoculum is large, but comparable with ampicillin in activity when a smaller inoculum is used.

Against *P. mirabilis*, carbenicillin shows the same pattern of activity as does ampicillin, that is, penicillinase-producing strains are resistant while non-penicillinase-producing strains are highly sensitive. Against strains of *P. morganii*, *religiosi*, and *vulgaris* carbenicillin is interesting in that many such strains which are resistant to ampicillin are relatively sensitive to carbenicillin. This would appear to be due to the greater stability of carbenicillin to the penicillinase produced by these species of *Proteus*.

**Effect of serum on activity.** Carbenicillin is not highly bound to serum proteins. Sensitivity tests carried out in

broth containing 95 per cent human serum show that the activity of carbenicillin is not significantly diminished by the presence of serum, and determinations by an ultra-filtration technique show that 53 per cent of the drug is free in human serum.

Fig. 1. Bactericidal activity of carbenicillin against *Pseudomonas pyocyanea*. ●, Control; ○, 50  $\mu\text{g/ml}$ ; △, 250  $\mu\text{g/ml}$ .

**Disk sensitivity testing with carbenicillin.** Using 6 mm paper disks containing 100  $\mu\text{g}$  carbenicillin, all strains of *Ps. pyocyanea* tested in this laboratory have given zones of inhibitions of 12–20 mm with a heavy inoculum and zones of 18–30 mm with a dilute inoculum. With a heavy inoculum a number of colonies can usually be seen within the zone of inhibition, although when these colonies are picked off and re-tested they show the same sensitivity as the original culture and again give rise to a number of colonies within the clear zone of inhibition.

In the case of Gram-negative bacilli other than *Pseudomonas*, for example, *E. coli* and *Proteus* species, a 25  $\mu\text{g}$  disk would be suitable for sensitivity testing. Using a heavy inoculum, inhibition zones of 20 mm or more are usually obtained with strains which are inhibited by 5  $\mu\text{g/ml}$ . carbenicillin.

## Animal Studies

**General pharmacology.** Carbenicillin in doses up to 500 mg/kg intravenously had no marked effects on the cardiovascular and respiratory systems and the autonomic nervous systems of cats. At 500 mg/kg there was a slight

transient hypotensive effect which disappeared within 10–20 min.

**Absorption, distribution and metabolism.** Carbenicillin is poorly absorbed orally in the rat, but after intramuscular injection the penicillin becomes distributed throughout the body in a similar manner to other penicillins. Relatively high concentrations of the penicillin appear in the alimentary tract after intramuscular administration. Chromatographic examination of intestinal contents and tissue confirms the presence of the drug in the gut. This is probably due to the excretion of bile containing carbenicillin into the intestine.

In order to determine the biliary excretion, the bile ducts of rats were cannulated with 'Polythene' tubing (0.4 mm diameter) and the animals placed in metabolism cages, after being injected with 100 mg/kg carbenicillin intramuscularly. Bile specimens were obtained at intervals of 1 h over a period of up to 6 h after dosing. A total of 15.1 per cent of the penicillin was recovered from the bile during this period and 28.8 per cent of the antibiotic was recovered from the urine over a period of 4 h.

Following intramuscular injection of carbenicillin into rabbits at a dose of 500 mg/kg, samples of cerebrospinal fluid were withdrawn from the cisterna magna at 0.5, 1, 2 and 4 h and assayed. No antibiotic was found in the cerebrospinal fluid, indicating a failure of carbenicillin to penetrate the blood-brain barrier.

When given subconjunctivally, 0.5 ml. of both 10 per cent and 25 per cent solutions of carbenicillin in xylocaine/adrenaline solution B.P. gave concentrations up to 200 µg/ml. in the aqueous humour. Detectable concentrations were present for a longer period after the injection of the 25 per cent solution.

**Prolonged toxicity studies in dogs.** Thirty pedigree beagle dogs were used in the study. They were housed singly and fed with weighed quantities of dry diet twice daily, the food intake being calculated. Unlimited supplies of water were provided and, in addition, one-third of a pint of milk daily was available.

The animals were divided into five groups of three males and three females and were dosed as follows: group 1, commencing at 2 g/kg/day subcutaneously; group 2, 500 mg/kg/day subcutaneously; group 3, 250 mg/kg/day subcutaneously; group 4, 250 mg/kg/day intravenously; group 5, controls dosed with saline subcutaneously.

Carbenicillin was dissolved in physiological saline so that 1 g of carbenicillin was contained in 1.5 ml. of saline; the solution was made up freshly each day. The dogs were weighed once a week and the dose to be given during the ensuing week was calculated. The intravenous injections were given into the veins of the forelimb. The duration of dosing was 3 months for the subcutaneous groups and 1 month for the intravenous group.

Clinical symptoms were recorded daily, body weight once a week, food intake twice daily and ophthalmoscopic examination was carried out just before the dogs were killed. Haematological, biochemical, urinalysis and serum glucose concentration tests were performed on all dogs, once before dosing began and at 4, 8 and 13 weeks after dosing had begun.

All animals which died during the experimental period were examined after death and all the remaining animals were killed at the end of the dosing period. The internal organs were examined macroscopically and the brain, pituitary, heart, lungs, liver, spleen, pancreas, thymus, prostate/uterus, kidneys, thyroids, adrenals and gonads were removed and weighed. Portions of these tissues, together with sections of aorta, trachea, cervical and mesenteric lymph nodes, salivary glands, various levels of the alimentary tract, gall bladder, skin from injection sites, sciatic nerve, optic nerve, eye, skeletal muscle and bone marrow, were fixed and stained with haematoxylin and eosin. Additional sections of the liver and kidney were specially stained for fat.

There were no deaths from drug toxicity and only one

accidental death. There were no observable changes in general physiology, apart from slight local swelling of tissues around the sites of intravenous injections. Severe local swelling, pain, "cyst formation", but little ulceration, occurred when the subcutaneous route was used for the highest dose level. At 500 mg/kg/day, moderate disturbances resulted, whereas at 250 mg/kg/day there was only minimal evidence of local irritation.

There was some suppression of weight gain associated with a suppression of appetite at the highest dose level by subcutaneous injection, the animals receiving 6–8 g/kg/day. Local irritation rather than the systemic absorption of carbenicillin may have been the chief cause of this loss of weight gain, because while at 250 mg/kg/day by intravenous injection there was no weight suppression, less weight was gained by the same dose level given by the subcutaneous route.

A slight reduction in the serum potassium concentration occurred after 4 weeks at the highest subcutaneous dose level but was not seen later. In two dogs dosed for 4 weeks by intravenous injection at 250 mg/kg, there was some reduction in the concentrating power of the kidney. No effect on the kidney was found in a repeat test at 500 mg/kg intravenously.

Only local tissue damage was found on macroscopic examination at post-mortems and only local irritant reactions at the injection sites were found on histological examination. There was no evidence of organ damage.

**Prolonged toxicity studies in rats.** Doses of 250, 500 and 1,000 mg/kg carbenicillin were given subcutaneously to groups of thirty Sprague-Dawley caesarian-derived rats from the Charles River Breeding Laboratories, Wilmington, Massachusetts, fifteen males and fifteen females to each group, over a period of 13 weeks. The rats had access to weighed quantities of autoclaved Spillers 'Laboratory Animal' diet and to tap water. The solutions of the drug were prepared freshly each day and administered in a volume of 0.4 ml./100 g. Two injection sites were chosen for each rat, each site being used on alternate days. Throughout the course of the test a record of food consumption and body weight change was kept daily and the mean weekly intake per rat calculated. Urinalysis and haematology were carried out at the beginning of dosing and at 4, 8 and 12 weeks. At the end of the test all the animals were killed by anaesthetization with ether followed by exsanguination.

After the post-mortem examination, all the essential organs were prepared for histological examination. No histological or clinical effects attributable to the drug were detected throughout the course of the dosing apart from a trend in the top group towards a slight fall in the red blood count.

**Local irritancy studies.** The local action of carbenicillin was determined in the rabbit eye after subconjunctival injection and after topical application. In the first series of experiments two animals each were allocated to groups which received 0.2 ml. of a 25 per cent, 10 per cent or 1 per cent solution of carbenicillin, respectively. The 25 per cent solution of carbenicillin was prepared in xylocaine/adrenaline solution B.P., in order to reduce the painful response to the hypertonic solution. All the animals were observed twice daily for one week after the injections and any inflammatory responses were recorded. At the end of the period the rabbits were killed and the eyes and surrounding tissues removed for histological examination. The 10 per cent and 1 per cent solutions produced very little reaction with only a very mild inflammatory response, and the histological examination showed no damage. The 25 per cent solution, however, caused inflammation with leucocytic infiltration within 3 h of the injection. Within 48 h, however, the reaction had subsided and by the end of the test period there was no evidence of inflammation.

0.2 ml. of a 25 per cent solution of carbenicillin was applied for 2 min to the eyes of rabbits after which the

antibiotic was washed out with warm saline. The eyes of the control animals were treated with saline in the same period of time. The animals were treated twice a day for 3 days. They were then killed on the fourth day and the tissues removed for histological examination. After the first application of the 25 per cent solution there was a slight inflammation of the conjunctiva in one animal which lasted 24 h, but on post-mortem examination no damage was observed; otherwise local application caused no ill effects.

Carbenicillin was also given by intramuscular injection. Twelve rabbits were closely shaven across the dorsum and two injection sites chosen in each of two sacro-spinalis muscles of the back. One site was injected with 1 ml. of a 50 per cent concentration of carbenicillin in saline and the other with 1 ml. of saline. 4 days later the animals were killed and the treated areas prepared for histological examination. At all the sites which received the drug there was fibrolysis and necrosis accompanied in five animals by oedema.

**Effects on pregnant rats.** Sprague-Dawley caesarian-derived rats from the Charles River Breeding Laboratories, Wilmington, were used. The animals were allowed to mate, the day of mating being judged by the appearance of the vaginal plug. Dosing began on day 6 of pregnancy up to and including day 15. Three groups of twenty females were taken, group 1, the control group, being dosed with saline, while groups 2 and 3 received respectively 100 and 500 mg/kg carbenicillin in physiological saline, subcutaneously. The volumes of all injections were standardized to 0.2 ml./100 g body weight. The animals were given free access to Spillers 'Laboratory Animal' diet and to tap water and were closely observed throughout pregnancy. On day 21 the animals were killed and the uterine contents examined for the number of viable young, resorption sites, litter weight and foetal abnormalities. The young were examined externally after removal from the uterus, one-third being retained for detection of visceral abnormalities and the remaining two-thirds for subsequent dissection of animals followed by clearing and staining of the skeleton by alizarin to detect skeletal abnormalities.

No obvious signs of maternal reactions were observed during the test, but treatment with carbenicillin was associated with a slight retardation in body weight gain. Conception rate, average litter weight and size were not, however, significantly affected by the treatment and there was no incidence of abnormalities due to the drug.

**Effect on pregnant mice.** Groups of twenty-two mice were mated and treated in a similar way to the rats in the rat pregnancy study except that the animals were killed on the seventeenth day of pregnancy when the uterine contents were similarly examined.

Carbenicillin had no effect on the body weight changes in the mouse, and conception rate, litter size and foetal loss were unaffected at either dosage. There was also no incidence of abnormalities and skeletal deformities due to the drug treatment.

**Peri- and post-natal development of the rat.** Tests were carried out to determine the effect of carbenicillin on male and female rats before mating and through gestation and lactation to the twenty-first day after birth. Daily doses of 100 and 500 mg/kg of carbenicillin were administered subcutaneously throughout this period.

Parent animals were unaffected, as assessed by daily observation, body weight change, conception rate, length of the gestation period, and parturition. Litter size, litter and mean pup weights and pup loss of rats receiving 500 mg/kg were unaffected at birth or after 4 or 21 days. The increased pup mortality recorded at the lower dosage of 100 mg/kg was therefore considered to be unrelated to the treatment. No abnormal pups were found.

We conclude that carbenicillin at dosages of 500 mg/kg and below does not adversely affect the peri- and post-natal development of the rat.

## Absorption and Excretion in Man

The following absorption and excretion studies were undertaken in order to determine a suitable dosage and route of administration for a proposed clinical trial.

**Assay methods.** The concentration of carbenicillin in serum and in urine was determined by the cup-plate biological assay method. Details of the technique were as described previously<sup>1</sup> except that *Pseudomonas pyocyanea* NCTC 10490 (Ellsworth strain, 1973) was used as the test organism. *Sarcina lutea* and *Staphylococcus aureus* are unsuitable as assay organisms because carbenicillin contains a small amount of benzylpenicillin and this may appear in the serum and urine together with the carbenicillin. Because *Sarcina lutea* and *Staph. aureus* are many times more sensitive to benzylpenicillin than to carbenicillin the presence of traces of benzylpenicillin may invalidate the assay. *Ps. pyocyanea* NCTC 10490, on the other hand, is sensitive to carbenicillin but is relatively resistant to benzylpenicillin. The culture is unusually sensitive to carbenicillin, showing an MIC of about 1.25 µg/ml., and it is possible to assay concentrations of carbenicillin as low as 2.5 µg/ml. using this strain, while benzylpenicillin at concentrations of up to 500 µg/ml. fails to show any zone of inhibition. Standard solutions of carbenicillin from 1–100 µg/ml. were prepared in human serum, and where necessary the serum samples were diluted with human serum to give a concentration within this range. For the assay of urine samples the standard solutions of carbenicillin were prepared in 0.05 molar phosphate buffer pH 7.0 and urine samples were also diluted as required using the same buffer.

**Oral administration.** After a dose of 500 mg carbenicillin in gelatine capsules to healthy adults in the fasting state, no carbenicillin (that is, <1.0 µg/ml.) could be detected in serum samples taken at 0.5, 1, 2, 4 and 6 h after administration.

Carbenicillin was detected in the urine, which was collected over the 6 h period after the administration of the drug, but the quantity present in the urine amounted to less than 1 per cent of the dose administered. It would appear, therefore, that carbenicillin is not absorbed to any extent when given by mouth.

**Intramuscular administration.** Carbenicillin was administered by intramuscular injection to healthy adults in doses of 250 mg, 500 mg and 1 g dissolved in water for injection. The 250 mg dose was dissolved in a volume of 1 ml. and the 500 mg and 1 g doses were administered in a volume of 2 ml. The serum concentrations obtained are shown in Table 5.

Table 5. MEAN SERUM CONCENTRATIONS OF CARBENICILLIN AFTER INTRAMUSCULAR INJECTION IN ADULT VOLUNTEERS

No. of subjects	Dose (mg)	Serum concentration (µg/ml.)				
		0.5 h	1 h	2 h	3 h	6 h
10	250	5.9	7.0	5.7	2.6*	
9	500	13.7	17.7	13.2	—	2.0
16	1000	21.6	25.3	22.1	—	10.9

It will be seen that intramuscular injection resulted in a high concentration of carbenicillin in serum with a peak at about 1 h after injection. Thereafter the serum levels fell relatively quickly and about 80 per cent of the dose appeared in the urine over the first 6 h.

Table 6 shows results for the effect of probenecid on the serum levels and the urinary excretion of carbenicillin.

Table 6. EFFECT OF PROBENECID ON SERUM LEVELS AND URINARY EXCRETION OF CARBENICILLIN IN HEALTHY ADULT VOLUNTEERS

	No. of subjects	Mean serum concentration (µg/ml.)					Percentage of dose excreted in urine over 0–6 h
		0.5 h	1 h	2 h	4 h	6 h	
With probenecid*	10	25.7	30.9	48.0	27.4	19.4	49
Without probenecid	10	26.8	29.4	23.2	10.8	3.3	84

\* Carbenicillin dose 1.0 g by intramuscular injection.

\* 1 g 1 h and 10 h before administration of carbenicillin.

Probenecid was administered to healthy adults in a dose of 1 g 10 h, and again 1 h, before the intramuscular administration of 1 g carbenicillin. It will be seen that probenecid produced a substantial increase in the peak levels of carbenicillin obtained in serum and the rate of elimination of the drug from the serum was markedly diminished.

Chromatography of human urine, obtained after intramuscular administration of carbenicillin, indicated that the drug does not undergo any substantial metabolism in the body.

**Intravenous administration.** Results are shown in Table 7 for the serum levels obtained after intravenous injection of 1 g carbenicillin. This amount was dissolved in 10 ml. water and administered over a period of 3 min. Although the drug was eliminated rapidly from the blood it will be seen that serum levels in excess of 100 µg/ml. were obtained during the first 30 min after administration of this dose.

Table 7. SERUM CONCENTRATION OF CARBENICILLIN AFTER INTRAVENOUS ADMINISTRATION OF 1 g

Subject	Serum concentration (µg/ml.)					
	0-25 h	0.5 h	1 h	2 h	4 h	6 h
A	140	127	60	28	3.7	<3.0
B	140	114	55	23	4.4	<3.0

**Carbenicillin levels in serum and in urine in relation to antibacterial activity.** As a result of the extensive elimination of the drug by way of the kidneys, relatively high concentrations of carbenicillin are obtained in the urine. In the studies involving a dose of 500 mg by intramuscular injection, the concentration in the urine collected over the first 6 h was generally 1,000-2,000 µg/ml. This is considerably in excess of the concentration of drug required to inhibit the growth of *Ps. pyocyanea*. On the other hand, it is questionable whether intramuscular injection of 1 g carbenicillin at intervals of 6 h, even in conjunction

with probenecid, would result in tissue concentrations which would be inhibitory towards typical strains of *Ps. pyocyanea*. The minimum inhibitory concentration of carbenicillin for most strains of *Ps. pyocyanea* appears to be 50-100 µg/ml., and although the drug is not highly bound to serum protein (about 50 per cent is bound) it would probably be desirable to achieve serum levels somewhat in excess of 100 µg/ml. This can readily be attained by intravenous administration.

In addition to the activity which carbenicillin shows against *Ps. pyocyanea*, the drug is active against other pathogens, including *E. coli*, and also strains of *Proteus morganii*, *P. rettgeri* and *P. vulgaris* which are generally resistant to ampicillin. On the basis of the *in vitro* sensitivity of these latter organisms to carbenicillin, the serum concentrations achieved by intramuscular administration of the drug might be adequate and the levels attained in urine are again greatly in excess of the minimum inhibitory concentrations.

The results obtained in these studies suggested that for clinical trials on the therapeutic effectiveness of carbenicillin in urinary tract infections, a suitable dosage might be 1.0 g by intramuscular injection at intervals of 6 h. The treatment of pseudomonas septicaemia, wound infections and tissue infection in general would require the intravenous infusion of carbenicillin (with or without probenecid) in order to attain inhibitory serum and tissue concentrations.

We thank our colleagues for experimental assistance and Mr F. P. Doyle for advice and guidance. We also thank Dr A. N. Worden and his colleagues at Huntingdon Research Centre for their assistance with the long-term toxicity studies on carbenicillin (BRL2064).

London School of Hygiene and  
Tropical Medicine

An apparatus is described which will provide a continuous and regular aerosol of 5µ particles of polystyrene labelled with chromium-51. The elimination of the radioactively labelled particles from the lungs after a single inhalation by human beings is followed by external gamma-ray measurements.

In order to estimate the dose of radiation to the lungs from radioactive particles in inhaled air, it is necessary to know the proportion of particles deposited in the lungs and the duration of their retention. For insoluble particles, the site of deposition is important, because the material deposited in the ciliated regions of the upper airways is rapidly removed to the pharynx and eliminated by way of the intestinal tract, whereas those particles which penetrate to the alveoli are removed much more slowly and may be permanently retained in the lymph nodes. The site of deposition depends on the size and mass of the particles and on the depth and flow rate of the breathing pattern. These variables must be controlled so far as possible to obtain meaningful experimental results.

This article reports experiments in which a monodisperse aerosol of particles 5 µm in diameter was tagged with radioactivity so that measurements could be made by external counters over the lungs. On each occasion the subjects inhaled only a single breath of the aerosol and the particles could only penetrate the airways as far as they were carried by the volume of the inhaled air, which varied between 140 and 500 ml. in the different experiments.

Spherical translucent particles of polystyrene of about unit density were continuously generated from xylene solution by a spinning disk<sup>1</sup> in a chimney which formed part of the breathing apparatus (Fig. 1). The concentration of polystyrene in the xylene was 0.2 per cent by

Fig. 1. Diagram of apparatus. (1) Chimney; (2) constant head feed of polystyrene solution; (3) breathing tube and mouthpiece; (4) one-way stop valve; (5) to spirometer; (6) filter for expired air; (7) hypodermic needle; (8) path of drying droplets; (9) absolute filter; (10) 40 L/min air; (11) drive air for rotor; (12) rotor; (13) shockproof mounting; (14) sealed box, (15) exhaust air from rotor drive.

weight and the rate of rotation of the disk was  $3 \times 10^4$  r.p.m. Liquid droplets of 40  $\mu$ m diameter were formed, from which the xylene rapidly evaporated leaving solid spherical polystyrene particles of 5  $\mu$ m diameter.

The particles were tagged with chromium-51, which has a radioactive half-life of 28 days, and decays by  $K$  capture, emitting a 0.323 MeV  $\gamma$ -ray in 9 per cent of its disintegrations. The chromium was dissolved in the xylene as chromium acetyl-acetonate, and was incorporated in the polystyrene particles. Not more than 1 per cent of the activity was leached out when the particles were suspended in water for 4 months.

The number of particles in the inhaled aerosol was about  $2 \times 10^4$ /l. and the activity a few  $\mu$ c./l. An initial lung burden of about 1  $\mu$ c. chromium-51 (0.09  $\mu$ c. of  $\gamma$ -ray activity) was obtained. The advantage of using a  $K$ -capture isotope was that the dose to the lung was not more than 0.5 mrad/day, which is only three times the dose rate from the natural background.

The concentration of xylene in the inhaled air was about 10 mg/l. The maximum permissible concentration<sup>2</sup> for continuous breathing is 0.9 mg/l., but the subjects inhaled a single breath only, so no toxic effects should have arisen. Nevertheless, it was desirable to exclude the possibility of some irritant or anaesthetic effect of the xylene vapour on the cilia, and an alternative method was developed for inhaling particles without xylene. The particles were generated in the usual way and collected by impaction in water containing a small quantity of surface active agent. The suspension was then sprayed through an air-blast atomizer. The disadvantage of this method was that it was wasteful of activity—the yield of aerosol being very small—and it was not possible to measure the retained activity so accurately. The results with subjects who inhaled aerosols generated by both methods, however, showed no significant differences.

It is difficult to measure the inhaled volume and aerosol concentration accurately, particularly when the particles

have appreciable settling velocities. The following technique was adopted. The spinning disk was set running, and a sample of the aerosol examined to ensure that the particle size and concentration were correct. Meanwhile, the subject inhaled air from the atmosphere at normal breathing level and exhaled into a spirometer, adjusting his tidal volume by watching the spirogram. At the end of an expiration, a tap was turned so that the next inhalation was of aerosol. This breath was held for 10 sec, to increase the deposition of particles, after which a total expiration was made through a filter (Fig. 1). The activity of the inhaled air was estimated from 500 ml. samples taken from the chimney immediately before and after the inhalation through a tube similar to the breathing tube. The activity of the exhaled air was deduced from the counting rate from the filter. In estimating the activity which entered the trachea, 60 ml. was subtracted from the inhaled volume to allow for the volume of the mouthpiece, mouth and pharynx.

Immediately after the inhalation, the subject washed out his mouth to remove any particles deposited there. Measurements of radioactivity *in vivo* were made in an enclosure with lead walls 11 cm thick. The  $\gamma$ -ray detectors were two thallium activated crystals of sodium iodide, 15.2 cm in diameter and 8.9 cm thick. They were shielded by cylindrical lead collimators with walls 1.3 cm thick, which extended 8 cm in front of the crystal faces. The detectors were placed dorsally and ventrally on the mid-line of the chest of the supine subject. The upper detector was positioned with the lower edge of the collimator over the caudal end of the sternal body and at a height such that the body just touched the collimator at inspiration. The lower detector was positioned directly below the first, with the top of the collimator 1 cm below the 1 cm thick plastic bed on which the subject lay.

The collimation was designed to minimize the response from activity in the abdomen without reducing too much the sensitivity to activity in the lung. For one subject measurements were also made with the detectors displaced 7 cm laterally and 3 cm nearer the head. The elimination rates were not significantly different from those observed with the counters positioned as normal. The geometrical arrangement of the counters minimized the changes in counting efficiency with changes in distribution of activity *in vivo*. In order to calibrate the detectors the counting rates from a standardized "point" source of chromium-51 were measured in a number of simulated distributions in the lung phantom consisting of 'Mix D' X-ray phantom wax and air spaces.

Independent estimates of the activity retained initially were obtained from the measurements of radioactivity in the lungs, from the activity of the inhaled and exhaled air and from faeces over the first 3 days (after 3 days there was insignificant activity in the abdomen). These agreed quite well, as illustrated by the results from subject D. V. B.

Activity inhaled in 440 ml.	0.92 $\mu$ c.
Activity exhaled	0.02 $\mu$ c.
Retention by difference	0.90 $\mu$ c.
Retention estimated from lung counters	0.97 $\mu$ c.
Faecal excretion in first 3 days	0.31 $\mu$ c.
Loss from lung in 3 days (Fig. 3)	25 per cent
Retention from excretion data	1.2 $\mu$ c.

In another subject the activity in urine 20 days after the inhalation was measured, and was found to be below the limit of detection (less than a twentieth of the rate of loss of activity from the lung at that time). This was considered to be evidence that the activity was fixed in the particles.

The elimination of the labelled particles from the lungs of the experimental subjects is shown in Figs. 2 and 3 on a semi-log plot. The results represent the sum of the counts from the crystals above and below the chest and are corrected for radioactive decay of chromium-51 and normalized to unit initial deposition in the lungs. Fig. 2

refers to the first series with xylene vapour present in the aerosol and Fig. 3 to the later series in which the particles were sprayed from a water suspension. It appears that the xylene vapour inhaled with the particles in the first series of experiments made little or no difference to either phase of elimination, so that the two series can be regarded as duplicates. The exhaled activity in all cases was less than 10 per cent of the inhaled activity, and the graphs therefore approximate to the proportion of the inhaled dose which is retained.

The elimination of the particles can be divided into two phases. In the first phase (10–20 h) a fraction of the initial burden was eliminated, the fraction depending on the volume of the inhalation. There was no evidence of a very rapid initial removal with a half-life of the order of 30 min as observed by Albert and Arnett<sup>3</sup> and by Morrow<sup>4</sup>. On the contrary, in several cases the removal during the first 3 h was very slow.

The present results were obtained with a monodisperse aerosol and with an artificial breathing pattern. With normal breathing and only short pauses between breaths, sedimentation of particles would be less. At high flow rates the large particles of a heterodisperse aerosol are likely to impact in the upper respiratory tract. The activity of the particles is, of course, proportional to the cube of their radius, so that measurements of activity would tend to show the fate of the larger particles. With normal breathing, a larger proportion of the particles may reach the alveoli than in the present experiments

Fig. 2. Elimination of particles inhaled with xylene vapour; ----, 120 day half-period;  $\Delta$ — $\Delta$ , D.V.B. 500 ml.;  $\times$ — $\times$ , A.C.C. 500 ml.;  $\circ$ — $\circ$ , M.L.T. 250 ml.;  $\bullet$ — $\bullet$ , D.C.F.M. 140 ml.

Fig. 3. Elimination of particles inhaled with water vapour; ----, 120 day half-period;  $\Delta$ — $\Delta$ , J.R. 500 ml.;  $\times$ — $\times$ , A.C.C. 500 ml.;  $\circ$ — $\circ$ , M.L.T. 250 ml.

because the dead space is not normally completely cleared at each expiration.

The slow second phase of elimination shows half-lives of 150 days–300 days in the four subjects studied as compared with 120 days adopted by the International Commission of Radiological Protection in 1959 for insoluble particles. It is assumed that this phase represents the elimination of particles that had been deposited in alveolar regions. If ciliary stasis were present in significantly large areas of the upper respiratory tract this assumption would require modification.

Because the subjects inhaled only a single breath, the particles deposited during the breath holding period must have done so on the nearest mucosal wall and thus acted as markers to show how far the air had penetrated into the lung during inspiration. Such information cannot be obtained during steady state breathing unless both the extent of air mixing and the number of particles remaining in the dead space air at the end of expiration are known. If the fraction of activity eliminated during the initial fast phase is taken to represent particles deposited from air filling the ciliated regions at the end of inspiration, and the inhaled volume is known, then an estimate of the effective volume of the ciliated airways can be made, as shown in Table 1.

If 40 ml. (volume of mouth and pharynx) are added to the figures in the last column of Table 1, estimates of the effective dead space are obtained which are very similar to measurements of effective dead space by the single breath method<sup>5</sup>. It is also clear from Table 1 that unit

Table 1

Subject	Volume of aerosol inhaled (ml.)	Volume of aerosol entering trachea (ml.)	Fraction retained with half-life > 50 days	Volume from which particles eliminated with short half-life (ml.)
D. V. B.	500	440	0.75	110
A. O. C.	500	440	0.55	180
M. L. T.	250	190	0.52	90
D. M.	140	80	0.25	60
J. R.	500	440	0.75	110

density spheres  $5\mu$  in diameter easily penetrate to the alveolar regions of the lung and are not quantitatively removed by sedimentation or by impaction in the upper airways.

It is concluded that the elimination of particles from the respiratory tract has two main phases. The rapid phase corresponds to the removal of particles initially deposited on the ciliary mucosa and the slow phase to those particles which have reached the non-ciliated

regions. The rapid phase takes 10–20 h and the slow phase has a half-period of 150–300 days. The fraction of inhaled particles deposited on the two regions depends on the inhaled volume. The effective volume of the ciliated regions can be estimated by a single breath technique, but demands an accurate measurement of the inhaled volume. Because the site of deposition is also a function of the particle size it is essential to use uniform aerosols in such experiments.

## Dynamics of Organochlorine Insecticides in Vertebrates and Ecosystems

by

J. ROBINSON

Shell Research Ltd., Tunstall Laboratory,  
Sittingbourne, Kent

The dynamics of the diffusion of organochlorine pesticides in ecosystems can be described by a model based on the theory of sets. The model shows that research which relies on measurement of the pesticide at different periods of time can lead to misleading conclusions.

A CONSIDERABLE amount of information is available about the concentrations of organochlorine compounds in the tissues of experimental animals that have been exposed to organochlorine insecticides under controlled conditions; the two insecticides that have been studied most intensively are DDT and dieldrin. The tissues of animals that have been exposed to DDT (either as the technical material or as *pp'*-DDT) contain *pp'*-DDT, *pp'*-TDE and *pp'*-DDE, and the hydrophilic metabolite DDA is found in the urine<sup>1</sup>. After exposing animals to dieldrin (or HEOD, the major insecticidal constituent of technical dieldrin) the tissues are found to contain HEOD and smaller amounts of polar metabolites<sup>2</sup>. The relatively slow rate of elimination of *pp'*-DDT and its congeners, and HEOD, which is reflected in the storage of these compounds in animal tissues, particularly adipose tissue, has aroused considerable interest and comment. This interest has been intensified in recent years as a consequence of reports of their widespread occurrence in the biosphere. Small amounts of these compounds are found in the adipose tissue of the general population of several countries and in terrestrial and marine wildlife.

It is desirable that this large heterogeneous collection of empirical observations should be unified, if possible, on the basis of conceptual models. If such models can be established we shall have a better understanding of the possible effects of the use of these compounds on man and his environment. The dynamics of the uptake, distribution and elimination of these compounds by animals during long-term exposure will be considered first.

The following postulates are believed to be consistent with the experimental observations.

(i) The concentration of an organochlorine insecticide in a particular tissue is a function of the daily intake

$$c_{\alpha ij} = f_{\alpha ij}(a)$$

where  $c_{\alpha ij}$  is the concentration of the  $j$ -th insecticide in the  $i$ -th tissue of an animal of species  $\alpha$ , and  $a$  is the daily intake. The results of investigations of the concentrations

of DDT in the tissues of rats<sup>1</sup>, the adipose tissue of monkeys<sup>3</sup> and of man<sup>4</sup>; of HEOD in the adipose tissue of hens, steers, hogs and lambs<sup>5</sup>, the blood of dogs, the blood and adipose tissue of man<sup>6</sup>; and of heptachlor epoxide in the adipose tissue and milk of cows<sup>7</sup>, are consistent with this postulate.

The functional relationship is apparently curvilinear when the exposure to a single insecticide is over a wide range<sup>8,9</sup>, and simultaneous exposure to more than one of the organochlorine insecticides also changes the functional relationship<sup>9</sup>.

(ii) The concentrations in different tissues are functionally related

$$c_{\alpha ij} = g_{\alpha ik}(c_{\alpha kj})$$

where  $c_{\alpha ij}$  and  $c_{\alpha kj}$  are the concentrations in the  $i$ -th and  $k$ -th tissues. Significant correlations have been found between the concentrations of DDT in the tissues of rats<sup>1</sup>, between the concentrations of HEOD in the tissues of rats and pigeons<sup>10</sup>, and in the blood and adipose tissue of man<sup>6,11</sup>, and these correlations are consistent with this postulate. Some of the correlations between the concentrations in different tissues are not significant, but this does not necessarily imply that there is no functional relationship in these cases: the experimental values include variations between individuals and are also subject to experimental error—both these variables reduce the size of the correlation coefficients and hence their apparent significance. It is further postulated that the functional relationship implies that there is a dynamic equilibrium in the distribution of pesticides in the tissues.

(iii) The concentrations of organochlorine insecticide in the tissues depend on the time of exposure

$$c_{\alpha ij} = h_{\alpha ij}(t)$$

Time-dependent concentrations have been found for DDT in the adipose tissues of rats<sup>12,13</sup>, monkeys<sup>3</sup>, cattle<sup>7</sup> and man<sup>4</sup>; for HEOD in the blood of dogs, the blood and adipose tissue of man<sup>6</sup>, and the subcutaneous fat of the quail<sup>13</sup>; for the isomers of BHC in the adipose tissue of

rats<sup>14</sup>; and for heptachlor epoxide in the adipose tissue of cows<sup>7</sup>. The relationship in all cases examined appears to be curvilinear and it is also postulated that  $h_{adj}(t)$  approaches a finite upper limit as  $t$  increases. There are indications that the concentrations may pass through a maximum and then decline<sup>11,12</sup>; the mechanism underlying this decrease of storage with continuing exposure is not clear; it may be a result of microsomal activation or a physiological change with age which varies the absolute or relative sizes of one or more of the body compartments.

(iv) When exposure ceases, the concentrations of organochlorine insecticides in the tissues decline and the rates of decrease at a given time are proportional to the concentrations in the tissues at that time

$$\frac{d}{dt}(c_{adj}) = -k_{adj}(c_{adj})$$

Decreasing concentrations in the tissues after the end of exposure have been found for DDT in the adipose tissue of cows<sup>11,12</sup>, monkeys<sup>3</sup>; for HEOD in the tissues of rats and pigeons<sup>10</sup>, in the adipose tissue of cows<sup>7</sup> and in the blood of man<sup>16</sup>; and for BHC isomers in the adipose tissue of rats<sup>14</sup>. In some cases a relationship of the semilogarithmic type appears to fit the results satisfactorily<sup>8,10</sup>, that is,  $dc/dt = -kc$ , corresponding to a pseudo-unimolecular rate of elimination. In other cases the experimental results deviate significantly from this simple relationship; some authors have transformed both the variates (concentration and time) to obtain rectilinear relationships, but these equations appear to have no theoretical basis and it is suggested that rate equations of the type

$$dc/dt = -\sum k_i c_i$$

are more appropriate. Given that the rate equations for the elimination process are of the latter form and that the experimental animal is a constant entity, then it may be shown that the accumulation curve

$$c_{adj} = h_{adj}(t)$$

will approach an upper limit (asymptote) in an exponential manner. The asymptote is a function of the daily intake (in accordance with the first postulate).

These four postulates are consistent with the compartmental models which have been used to explain the dynamics of the behaviour of drugs<sup>17</sup>, lipids<sup>18</sup>, inorganic ions<sup>19,20</sup>, etc., in animals, and it is proposed, therefore, that such a model, particularly the mamillary system with a central compartment (blood or plasma) and peripheral compartments that cannot interchange directly with each other, be used in the case of the organochlorine insecticides. The model must also include the enterohepatic circulation in view of biliary excretion of these compounds. The results available at present are not sufficient to establish the model in full detail, but experiments can easily be designed to give the information required to make appropriate tests of the model.

The symbols used above for the postulates have been used not only because of their economy, but also because they implicitly assume a basis in set theory. A compartmental model theory has been developed from set-theoretical principles<sup>21,22</sup>, and such principles are also thought to be helpful in the development of a theory of the dynamics of the behaviour of organochlorine insecticides in ecosystems. An outline of the concepts of set theory, with particular reference to biological systems, has been given by Rashevsky<sup>23</sup>. Before outlining such a model, it is appropriate to review some of the evidence, unfortunately somewhat scanty at present, obtained in studies of the distribution of residues of these compounds in the environment.

The concentration of DDT-type compounds in the adipose tissue of members of the general population of the United States has been approximately constant for some 10–15 years; the concentration of HEOD in the adipose

tissue and blood of the general population in Britain has been unchanged, within the limits of experimental error, since 1961; the concentration of HEOD in the livers of shags (from the colony in the Farne Islands) reaches a steady state at the age of about 1 year; the concentration of HEOD in the eggs of these birds has not increased over the period 1964–1966. All these observations are compatible with the concept of an upper limit of accumulation, related to the daily intake of DDT or HEOD, which has been suggested (fourth postulate). Again, the concentrations of HEOD and pp'-DDE in the eggs of the shags are significantly correlated ( $r_s = 0.71$ ,  $P < 0.001$ ), as also are the concentrations in the livers of these birds ( $r_s = 0.81$ ,  $P < 0.001$ ). These correlations are difficult to explain unless some common factors are involved in the uptake, distribution and storage of these compounds in the shags. It is also noteworthy that the concentrations of HEOD and pp'-DDE in the eggs of cormorants and shags are considerably greater than those found in nine other species of sea birds living in the same area. Some of the differences in the residues in eggs may arise from the different types of fish eaten by the birds, but it is considered plausible that the differences are caused partly, if not predominantly, by differences in the physiology of the birds, particularly in regard to the rates of elimination of these compounds. The compartmental model provides a set of consistent concepts capable of giving a unified explanation of these results of field studies.

An ecosystem may be defined as an area that includes living organisms and non-living (abiotic) components interacting to produce an exchange of materials and energy between the living and non-living components. The living organisms can be classified into three main groups: the producers (autotrophic organisms), the consumers (heterotrophic organisms), and the decomposers (saprophytes), heterotrophic organisms which break down the complex compounds of dead protoplasm and release simple substances that may be used by the autotrophic organisms. There is thus a cyclic exchange of matter and energy within the ecosystem.

The ecosystem may be regarded as a super-set with the trophic levels (corresponding to the producers, consumers and decomposers) as sets contained within the super-set. Individual species form sub-sets of the trophic levels, and individual organisms are members of the sub-sets

$$a \in S \subset T \in E$$

where  $a$  is an individual organism,  $S$  is the species to which the individual belongs,  $T$  is the trophic level and  $E$  the ecosystem; the symbols  $\in$  and  $\subset$  are the standard ones for "membership of" and "is contained in". The total annual biomass of a given trophic level is

$$\sum_{jk} m_{ijk}$$

and the total content of a particular insecticide in this trophic level is given by

$$\sum_{jk} m_{ijk} x_{ijk}$$

where  $m_{ijk}$  is the body weight of the  $k$ -th member of the  $j$ -th species in the  $i$ -th trophic level and  $x_{ijk}$  is the average concentration of the insecticide in the whole body of this individual.

At a given instant in time the total amount of the insecticide in the ecosystem is

$$(\sum_{ijk} m_{ijk} x_{ijk} + W)$$

where  $W$  is the mass of the insecticide in the non-living components (soil, water, air). In a completely isolated ecosystem the total mass of the insecticide will remain constant, although the instantaneous distribution between the trophic levels, etc., may vary, unless the insecticide is degraded either by biotransformation in the living organisms, or by chemical and/or physical processes in the abiotic components. Most ecosystems, of course, are

not isolated. The total mass of an insecticide in the  $i$ -th trophic level may increase as a result of transfer from the  $(i-1)$ th trophic level; it may decrease either by degradation of the insecticide within the  $i$ -th level or by transfer to the  $(i+1)$ th level. The total biomass in the  $i$ -th level may increase as a result of (a) migration into the ecosystem, (b) reproduction, and (c) growth of the organisms in that level. The chief factors leading to a decrease in the biomass are (a) migration from the ecosystem, (b) death of individuals, or (c) loss of weight by starvation. Precise information on these variables is not available except in a few very special systems, but this does not necessarily imply that no progress can be made in constructing a model. The system can be regarded as a black box with transfer functions that define the ratio between the input and output of mass or energy or insecticide residues. The trophic levels correspond to subdivisions within the black box; this suggested use of the black box is similar to that proposed for precursor-product relationships in the compartmental model<sup>24</sup>.

Some of the modes of change of the biomass will have concomitant effects on the total mass of an insecticide in a trophic level, for example, migration of individuals from the ecosystem decreases both the biomass and the mass of the insecticide in their trophic level. Growth of organisms will increase the biomass, but the food necessary for growth may result in a transfer of insecticide from the  $(i-1)$ th level. On the other hand, the death of an individual will decrease the biomass in the  $i$ -th level and, simultaneously, reduce the mass of insecticide. The latter will eventually be incorporated, with or without some degradation, into the saprophytic organisms, or returned to the abiotic components. The annual biomasses of the successive trophic levels become successively smaller (pyramid of mass), that is

$$\sum_{j \leq i} m_{(i-1)j} > \sum_{j \leq i} m_{ij}$$

Let the transfer of biomass from the  $(i-1)$ th trophic level in time  $\Delta t$  to the  $i$ -th level, as a result of the consumers in the latter, be

$$\sum_{j \leq i} \Delta m_{(i-1)j}$$

and let the increase of biomass in the  $i$ -th level be

$$\sum_{j \leq i} \Delta m_{ij}$$

consequent on this consumption. Then

$$\sum_{j \leq i} \Delta m_{(i-1)j} > \sum_{j \leq i} \Delta m_{ij}$$

(otherwise the pyramid of mass would not hold) and the amount of insecticide entering the  $i$ -th trophic level will be

$$(\sum_{j \leq i} \Delta m_{(i-1)j} - \sum_{j \leq i} \Delta m_{ij}) x_{(i-1)j}$$

The concentration of insecticide in the  $i$ -th level will increase unless the rate of loss of this compound from the  $i$ -th level is equal to or greater than its rate of accretion. The rate of loss of an insecticide from the  $i$ -th level is a function of the concentration in that level (because the loss depends on biochemical degradation or the death of organisms)

$$\frac{dx_{ij}}{dt} = -m(x_{ij})$$

but the relationship is probably more complex than that for the elimination from tissues (see fourth postulate). Further, this type of elimination process necessarily entails a finite upper limit of accumulation as time goes on, although, once again, the process is more complex than that in an organism because some of the insecticide transferred from the trophic level may be returned to it at a later date by way of the saprophytes and autotrophic organisms. The greater the ecological efficiency the smaller the value of the term

$$(\sum_{j \leq i} \Delta m_{(i-1)j} - \sum_{j \leq i} \Delta m_{ij})$$

The transfer functions in the model have been expressed in terms of mass, but it may be preferable to express the transfer functions in energy terms<sup>25,26</sup>, particularly if a significant proportion of the biomass of a trophic level consists of inorganic matter, for example, the shell of molluscs. The transfer of an insecticide between trophic levels would then be expressed as mass of insecticide per calorie of food consumed by the predators.

The model outlined here is also of assistance in interpreting the ecological consequences of the use of organochlorine insecticides and their consequent occurrence in the environment. The components of the environment that influence the fecundity, longevity and speed of development of an organism have been classified into five components by Browning<sup>27</sup>, one of which was "hazards". Maelzer<sup>28</sup> has criticized the term hazard as a description of a component of the environment because of the implication of general risk, and, as he points out, a particular circumstance is not always inimical in all circumstances. This distinction is also appropriate to the presence of organochlorine insecticides in the environment: the mere presence of these compounds does not necessarily entail harmful effects. There are threshold limits below which neither toxicological nor physiological effects (including behaviour) are observable.

The complete model has not yet been constructed but it is obviously complex and partially cyclic. It is clear, however, that great care is required in drawing conclusions about the behaviour of insecticides in ecosystems based on small numbers of observations, or on differences between samples from different trophic levels collected at different times. The advantage of the model, even in its present incomplete state, is that it presents a basis for assessing the validity of inferences drawn from field observations. Further, it enables sampling schemes to be devised so that the results may be used to test the validity of the model.

# A Cosmological Model with both Radiation and Matter

by

C. B. G. McINTOSH

Department of Mathematics,  
University of New England,  
Armidale,  
New South Wales

Previous models of the universe based on the "big bang" theory have set various times for the period when the density of matter became equal to the density of radiation. This model sets this limit at about 6.7 per cent of the present age of the universe and has an advantage because it explains what happens in the early as well as the late stages of the life of the universe.

THERE has been particular interest in recent years in the amount of radiation and matter in relativistic cosmological models. Penzias and Wilson<sup>1</sup> and Roll and Wilkinson<sup>2</sup> found an isotropic microwave background, which is believed by some<sup>3-5</sup> to be a remnant of the initial "big bang" or "fireball". Twenty years ago Gamow postulated<sup>6,7</sup> a model in which the energy density of radiation exceeds that of matter near the beginning of the universe. He says<sup>8</sup> that the matter density is less than the radiation density during about the first 10 per cent of the history of the universe and after this time exceeds the radiation density so that at present the latter can be neglected relative to the matter density. Thus different differential equations control the expanding universe for early time and for recent time. This is important because, as he shows, the thermal balance during the expansion is maintained by radiation and not by matter. According to Dicke *et al.*<sup>9</sup>, the densities become equal after about the first 0.01 per cent of the history.

Davidson<sup>9</sup> considers models in which the function  $S(t)$  of the line element

$$ds^2 = c^2 dt^2 - S^2(t) \left\{ \frac{dr^2}{1 - kr^2} + r^2 (d\theta^2 + \sin^2 \theta d\phi^2) \right\} \quad (1)$$

is given by  $S(t) = At^n$  and where the curvature  $k$  is zero and shows that, because the density  $\rho$  and pressure  $p$  are related by

$$\frac{p/c^2}{\rho} = \frac{2-3n}{3n} \quad (2)$$

the models with  $n$  slightly greater than  $\frac{1}{3}$  and slightly less than  $\frac{1}{3}$  are suitable models for early and late stages of the universe. The limits  $\frac{1}{3}$  and  $\frac{2}{3}$  give the ratio (2) as  $\frac{1}{3}$  (radiation only) and zero (matter only), respectively. His work, however, contains no mathematical way of changing from  $n = \frac{1}{3}$  to  $n = \frac{2}{3}$  as time increases. Gamow's model<sup>6-8</sup> changes from  $S \propto t$  to  $S \propto t^2$  for early and late stages.

This article proposes a cosmological model which covers both early and late stages. The model behaves like the  $n = \frac{1}{3}$  radiation model for early time and like the Einstein-de Sitter  $n = \frac{2}{3}$  matter model for late time.

Consider a model in which the function  $S(t)$  is defined by

$$\log S = \int \frac{2 dt}{3t - \frac{1}{\beta} e^{-\beta t} + \frac{1}{\beta}} + \text{const.}; \beta \text{ constant} \quad (3)$$

in a cosmologically flat space ( $k = 0$ ). Hubble's parameter and the deceleration parameter are

$$\frac{\dot{S}}{S} = \frac{2}{3t - \frac{1}{\beta} e^{-\beta t} + \frac{1}{\beta}} \quad (4)$$

and

$$q = \frac{1 + e^{-\beta t}}{2} \quad (5)$$

The density  $\rho$  and the pressure  $p$  are given by the substitution of equation (1) into Einstein's field equations so that

$$\frac{1}{3} K \rho c^4 = \left( \frac{\dot{S}}{S} \right)^2 = - \left( K p c^2 + 2 \frac{\ddot{S}}{S} \right) \quad (6)$$

Here

$$K \rho c^4 = \frac{12}{\left( 3t - \frac{1}{\beta} e^{-\beta t} + \frac{1}{\beta} \right)^2} \quad (7)$$

and

$$K p c^2 = \frac{4e^{-\beta t}}{\left( 3t - \frac{1}{\beta} e^{-\beta t} + \frac{1}{\beta} \right)^2} \quad (8)$$

giving

$$\frac{p/c^2}{\rho} = \frac{e^{-\beta t}}{3} \quad (9)$$

It will be shown later that  $\beta$  is of the order of  $10^{-17} \text{ sec}^{-1}$  so that  $\beta t$  remains small for about the first  $10^{14} \text{ sec}$  and  $e^{-\beta t}$  can be written as  $1 - \beta t$ . Also for  $t$  greater than  $10^{19} \text{ sec}$  the denominator of equation (4) is  $3t$  to a good order of accuracy. Thus for  $t < 10^{14} \text{ sec}$  and  $t > 10^{19} \text{ sec}$ ,

$$\frac{\dot{S}}{S} = \frac{1}{2t} \text{ and } \frac{2}{3t} \text{ sec}^{-1} \quad (10)$$

respectively,

$$q = \frac{2 - \beta t}{2} \rightarrow 1 \text{ and } \frac{1}{2} \quad (11)$$

respectively and

$$S \rightarrow At^{\frac{1}{2}} \text{ and } At^{\frac{2}{3}} \quad (12)$$

respectively. The term  $1/\beta$  in the denominator was included to make  $S(0) = 0$ . Also the ratio  $(p/c^2)/\rho$  in equation (9)  $\rightarrow \frac{1}{3}$  for  $t \rightarrow 0$  and  $\rightarrow 0$  as  $t \rightarrow \infty$ . Obviously there is still total conservation of energy in the model in the normal relativistic sense.

$$T^{\mu}_{;\mu} = 0 \text{ or } \frac{\partial(\rho S^3)}{\partial t} + \frac{p}{c^2} \frac{\partial S^3}{\partial t} = 0 \quad (13)$$

$\rho$  and  $p$  can be written as

$$p = p_{\text{radiation}} + p_{\text{motion}} = \frac{aT^4}{3} + p_{\text{matter}} v^2 \quad (14)$$

$$\rho = \rho_{\text{radiation}} + \rho_{\text{matter}} = \frac{aT^4}{c^2} + \rho_{\text{matter}} \quad (15)$$

Here  $p_{\text{motion}}$  is the pressure due to the random motions of the galaxies, equal to  $\rho_{\text{matter}} v^2$  (ref. 10), where  $v$  is the random radial velocity, observed by Hubble in 1936 to be less than 300 km/sec;  $a$  is Stefan's constant,  $7.6 \times 10^{-16} \text{ erg/cm}^2/\text{deg}^4$ ; and  $T$  is the radiation temperature of intergalactic space. Thus equation (9) can be rewritten as

$$\frac{p_{\text{r}}}{p_{\text{r}} + p_{\text{m}}} = e^{-\beta t} \text{ or } p_{\text{m}} = p_{\text{r}} (e^{\beta t} - 1) \quad (16)$$

where  $p_{\text{motion}}$  can be neglected as long as  $\rho_{\text{m}} < 10^7 \rho_{\text{r}}$  if  $v$  is approximately constant. As in Davidson's paper<sup>9</sup>, there must be a continual interchange of energy between matter and energy. No longer is  $\rho_{\text{m}} S^3$  a constant. Indeed, it increases with time because, defining

$$E_m(t) = \frac{1}{S^2} \left\{ \frac{d}{dt} (\rho_m S^3) + \frac{p_m}{c^2} \frac{dS^3}{dt} \right\} c^2$$

$$= \left( \dot{\rho}_m + 3 \frac{\dot{S}}{S} \rho_m \right) c^2 \quad (17)$$

this becomes (for  $p_m = 0$ )

$$E_m = \frac{12 e^{-\beta t}}{K c^2} \left( 3\beta t - 1 + e^{-\beta t} \right) \quad (18)$$

which is always greater than zero for  $t > 0$  so that  $\rho_m S^3$  increases. This  $E_m$  is, as in Davidson's paper, the total net rate of creation of material energy per unit volume over all frequencies at epoch  $t$ . Similarly

$$E_r = \left( \dot{\rho}_r + 4 \frac{\dot{S}}{S} \rho_r \right) c^2 \quad (19)$$

is the total net rate of transfer of matter energy per unit volume into radiation energy, so that

$$E_m + E_r = 0 \quad (20)$$

from equation (11) Davidson dismisses the possibility  $E_m > 0$  as "inapplicable to the universe as we observe it", but this does not seem necessarily so. That the rate of absorption of radiation per unit volume (with the resultant creation of matter) is greater than the rate of emission per unit volume at a given epoch does not mean that there will be no radiation. Indeed, the equations show that there will always be residual radiation, and that the amount can agree with that discovered.

For  $\beta t$  small and  $\beta t \gg 1$ ,

$$E_m = \frac{3\beta}{8 K c^2 t^2} \quad \text{and} \quad \frac{4\beta e^{-\beta t}}{4 K c^2 t^2} \quad (21)$$

respectively, so that  $E_m$  is quite small because  $\beta$  is of the order of  $10^{-17}$  (see later). For present  $t_0$ , the net rate of creation of matter from radiation is

$$\frac{1}{c^2} E_m = 3.2 \times 10^{-31} \text{ g/cm}^3/\text{sec} \quad (22)$$

It is interesting to compare this with the total creation rate in steady-state cosmology of  $3\rho_m H \sim 2 \times 10^{-48} \text{ g/cm}^3/\text{sec}$  (ref. 11).

It is assumed hereafter that the only contribution to  $p_{r,0}$  (the zero subscript denoting the present epoch) is that resulting from the background microwave flux already mentioned; that is, that which would be emitted by a black body at  $3.0 \pm 0.5^\circ \text{ K}$ . This is equivalent to a total radiation pressure of

$$c^2 p_r = a T^4 = 6.13 \times 10^{-13} \text{ dyne/cm}^2 \quad (23)$$

or radiation density of

$$\rho_r = 6.8 \times 10^{-34} \text{ g/cm}^3 \quad (24)$$

If the value  $(\dot{S}/S)_0 = 100 \text{ km/sec/Mpc} = 3.2 \times 10^{-18}/\text{sec}$  is used in equation (4), this together with equations (8) and (23) gives

$$e^{-\beta t_0} = 3.71 \times 10^{-4} \quad (25)$$

or

$$\beta t_0 = 10.20 \quad (26)$$

This implies that the present ratio of pressure to density is, from equation (9)

$$(p/c^2)/\rho = 1.24 \times 10^{-4} \quad (27)$$

Equations (4) and (26) now give

$$t_0 = 2.02 \times 10^{17} \text{ sec} = 6.3 \times 10^9 \text{ yr} \quad (28)$$

and

$$\beta = 5.06 \times 10^{-17}/\text{sec} \quad (29)$$

From equations (7) and (8)

$$K\rho_m c^4 = \frac{12(1 - e^{-\beta t})}{\left( 3t - \frac{1}{\beta} e^{-\beta t} + \frac{1}{\beta} \right)^2} \quad (30)$$

so that

$$\rho_{m,0} = 1.8 \times 10^{-28} \text{ g/cm}^3 \quad (31)$$

As this is two orders of magnitude higher than that of the observed density (ref. 12) of  $\rho_{m,0} \sim 7 \times 10^{-31}$  for the estimated mass of galaxies, the theory is satisfied only if there is a large preponderance of non-luminous matter.

It is interesting to compare  $\rho_m$ ,  $p_r$ , etc., for small and large  $t$ . For  $t < 10^{15} \text{ sec}$ , where  $e^{-\beta t}$  can be written as  $1 - \beta t$  to a reasonable order of accuracy, and for  $t > 10^{15} \text{ sec}$ , where  $e^{-\beta t}$  is almost zero, and  $3t_0 + 1/\beta = 3t$  to a good approximation,

$$K\rho_m c^4 = \frac{3\beta}{4t} \quad \text{and} \quad \frac{4}{3t^2} / \text{sec}^2 \quad (32)$$

respectively,

$$K\rho_r c^4 = \frac{3(1 - \beta t)}{4t^2} \quad \text{and} \quad \frac{4e^{-\beta t}}{3t^2} / \text{sec}^2 \quad (33)$$

respectively,

$$\rho_m = \beta t \rho_r \quad \text{and} \quad (e^{-\beta t} - 1) \rho_r \quad (34)$$

respectively, and

$$T = \sqrt{\left( \frac{3c^2(1 - \beta t)}{32\pi a G} \right)} \cdot \frac{1}{t} = 1.5 \times 10^{10} \frac{(1 - \beta t)^{1/2}}{t} \text{ } ^\circ\text{K}$$

$$\quad \text{and} \quad 1.7 \times 10^{10} \frac{e^{-\beta t/2}}{t^{1/2}} \text{ } ^\circ\text{K} \quad (35)$$

respectively (see also equation (10)). For  $\beta t \ll 1$ ,

$$K\rho_r c^4 = \frac{3}{4t^2} \text{ sec}^{-2} \quad \text{and} \quad T = \frac{1.5 \times 10^{10}}{t^{1/2}} \text{ } ^\circ\text{K} \quad (36)$$

None of  $\rho_m$ ,  $p_r$ ,  $\rho$  or  $\dot{S}/S$  has maximum or minimum values for finite positive  $t$ . They all decrease steadily with time.

The density of matter becomes the larger of the two densities after

$$t = 1.4 \times 10^{18} \text{ sec} \sim 6.7 \text{ per cent of present time} \quad (37)$$

that is, when

$$\rho_r = \rho_m = 1.4 \times 10^{-27} \text{ g/cm}^3 \quad (38)$$

and

$$T = 113 \text{ } ^\circ\text{K} \quad (39)$$

Notice that the value of 6.7 per cent of present time is less than Gamow's recent estimate<sup>3</sup> of about 10 per cent, his estimates for density and temperature being  $3 \times 10^{-28} \text{ g/cm}^3$  and  $50^\circ \text{ K}$ ; but the value is very much greater than that of Dicke *et al.*<sup>2</sup>.

The total density  $\rho$  is very nearly  $3 p/c^2$  (radiation) so long as  $e^{-\beta t}$  in equation (9) is very nearly 1. This depends on the order of accuracy required, but is nearly so for  $t < 10^{14} \text{ sec}$ .

The apparently *ad hoc* choice of  $S(t)$  in equation (3) was made to simplify the mathematics particularly in equations (4), (7) and (8). This choice of  $S$  changes the model from a  $n = \frac{1}{2}$  model to a  $n = \frac{2}{3}$  model as Davidson<sup>1</sup> had, and agrees with the initial radiation model required and the final model with the radiation density much smaller than the matter density, thus agreeing with present day observations. This model may provide a useful approach to the problem of building a cosmological model with both radiation and matter defined by a single metric and set of field equations.

I thank Dr N. W. Taylor for help and encouragement and for useful discussions on this work.

## ASTRONOMY

### Observations of Quasars using Interferometer Baselines up to 3,074 km

It has previously been demonstrated by the Jodrell Bank-Malvern interferometer that some quasars have angular diameters less than 0.025 sec of arc. These measurements were made with a baseline of 120 km at a wavelength of 6 cm (ref. 1).

It is not only desirable to improve still further the resolving power at centimetre wavelengths but, in view of existing theories which predict that the observed diameter of a quasar should increase with wavelength, it is important to achieve comparable resolution at longer wavelengths. This implies the use of very long baselines. With conventional interferometers using land lines or microwave links, it is difficult to preserve the phase of the signals for distances greater than a few hundred kilometres. Furthermore, it is difficult to compensate for the large and variable time delay between reception of the signals at the two telescopes. These difficulties have been overcome by the use of wide-band magnetic tape recorders and independent local oscillators controlled by rubidium frequency standards<sup>2</sup>.

With an interferometer of this type we have observed the quasar 3C 273B at a frequency of 448 Mc/s with a baseline of 3,074 km ( $4.6 \times 10^4 \lambda$ ). Assuming a Gaussian source model the visibility of the fringes indicates that the diameter of this source is less than 0.02 sec of arc at this frequency.

Observations at 448 Mc/s have also been made at a baseline of 183 km ( $2.7 \times 10^3 \lambda$ ) and fringes of high visibility observed for the sources 3C 273, 3C 286, 3C 287, 3C 309.1, 3C 345, NRAO 530, 3C 446 and OTA 102. The maximum angular diameter of these sources is therefore about 0.3 sec of arc. Fringes of low visibility were observed for the quasar 3C 454.3.

Although some sources showed large amplitude scintillations, the fringes for all sources were extremely regular, indicating that phase scintillation was small.

The instruments used for these observations were the 46 m telescope of the Algonquin Radio Observatory, the 25.6 m telescope of the Dominion Radio Astrophysical Observatory and the 18.3 m antenna of the Defence Research Telecommunications Establishment, near Ottawa. We thank the Defence Research Telecommunications Establishment for making available the 18.3 m antenna for some of these observations.

*Notes added in proof.* Subsequently, fringes were also observed from 3C 345 using the 3,074 km baseline.

### A Strong X-ray Source in the Vicinity of the Constellation Crux

This communication presents a preliminary report of the detection of a strong source of X-rays in the vicinity of the constellation Crux.

Two identical X-ray detection systems were included in the payloads of two Skylark rockets flown from Woomera, Australia (lat. = 30.9° S., long. = 136.5° E.), at 0032 U.T. on April 4, 1967 (Skylark SL 426), and at 2236 U.T. on April 20, 1967 (Skylark SL 425). The X-ray experiments on both flights operated successfully from ignition to re-entry 400 sec later. The data considered here will be those obtained when the rockets were at altitudes in excess of 100 km, because below this altitude the atmosphere is opaque to celestial X-rays in the energy range of interest.

The X-ray detection system on each rocket consisted of four LND proportional counters containing a xenon-methane (90 per cent to 10 per cent) mixture at 1 atm. The X-ray window of each counter was 12 cm<sup>2</sup>, and consisted of 14 mg/cm<sup>2</sup> (0.003 in.) of beryllium. The counters were calculated to have an efficiency which varied from 40 per cent at 2 keV to 98 per cent at 8 keV. The counters possessed energy resolutions of about 25 per cent full width half maximum (FWHM) when newly filled. The resolutions of some of the counters deteriorated with time, however, possibly as a result of contamination of the filling gas with electronegative material, and in the worst case were 70 per cent immediately before the flight (SL 426). Two counters used on SL 425 possessed the best energy resolution immediately before flight (~30 per cent) and for the purposes of this communication have been used to investigate photon energy spectra.

On each rocket, the counters were divided into two groups of two, each pair "looking" in one direction and having its pulse outputs combined through an equalizing network. The resultant pulse train was analysed by a two window pulse height analyser, with windows set at 2-5 keV and 5-8 keV. These windows were calibrated using the 5.9 keV X-rays from a source of iron-55. The counting rate data from the two energy windows corresponding to each pair of counters were telemetered to ground, as were the temperatures of various components. The geometrical configuration of the counters was such that about 75 per cent of the pulses due to relativistic cosmic rays were equivalent to greater than 8 keV energy deposition, and thus were rejected.

Collimators were placed in front of each of the counters to define its field of view, the angular resolutions being 10.5° FWHM in the direction of rocket spin and 35° FWHM in the plane containing the spin axis. The attitude of the rocket spin axis, and the phase of the rocket spin, were determined using optical, magnetic, and rate gyro data provided by the standard Skylark instrumentation unit. Four independent crossed-slit Sun sensors provided the angle between the solar and spin vectors, while a three-axis magnetometer permitted calculation of the angle between the magnetic and spin vectors; the two angles

Table 1. SUMMARY OF RESULTS FOR "CRUX" OBJECT

	SCO XR-1	"CRUX"
Intensity*		
SL 425 2-5 keV (o.p.s.)	200 ± 8	160 ± 7
5-8 keV (o.p.s.)	98 ± 5	33 ± 3
2-8 keV ratio "CRUX"		0.52 ± 0.04
Spectra	SCO XR-1	
SL 425 ratio 5-8 keV 2-5 keV	0.36 ± 0.03	0.20 ± 0.03
Position†		
SL 425: Right ascension	16.2 h	13.7 h
Declination	-15°	-63°
SL 426: Right ascension	16.3 h	13.5 h
Declination	-16°	-66°

\* No corrections have been applied for the efficiency of the counters. Absolute photon fluxes should not be computed from these counting rates until such corrections have been applied. (Errors shown are statistical).

† The position of SCO XR-1 is 16.28 h, 15.5 degrees (ref. 3).

Fig. 1. The counting rates observed as the detector scanned over *SCO XR-1*, the Sagittarius group of sources and the Crux object. The *SL 425* data refer to the 2-5 keV energy window while the *SL 426* data refer to the 2-8 keV energy range.

then yield the direction of the spin vector. Using these data the direction of viewing of the two pairs of detectors was determined for all times during each flight.

Fig. 1 shows representative X-ray counting rates obtained during both flights, and Fig. 2 summarizes the motion of the centre of the field of view of the X-ray detectors on the celestial sphere for these scans. Referring to the aspect solution (for example, Fig. 2), the directions of viewing corresponding to the various counting rate maxima have been calculated, and Fig. 2 presents the positions on the celestial sphere of the various X-ray sources thus determined. It is clear from this that in addition to the observation of X-rays from the well known Sagittarius cluster of X-ray sources, and the *SCO XR-1* object, both flights detected X-rays from an object at a high negative declination. In both flights the relative positions of the Sun and the magnetic vector were such that a less accurate position could be found for the new object than for *SCO XR-1*. This is reflected in the dispersion in the positions as seen in Fig. 2 and

Table 1. While the position of the object is still somewhat uncertain, for convenience we shall refer to it as the "CRUX" object, because the positions are in the vicinity of the constellation Crux.

Table 1 presents the data from the two energy windows corresponding to the pair of counters on *SL 425* which exhibited a pre-flight energy resolution of 30 per cent FWHM. There is a significant difference between the 5-8 keV/2-5 keV ratios corresponding to *SCO XR-1* and "CRUX" which suggests that the energy spectrum of "CRUX" is softer than that of *SCO XR-1*. The two window spectra from the other counter pairs are consistent with this qualitative conclusion, after allowance for the less favourable FWHM applicable to these other counters.

Comparing *SCO XR-1* and "CRUX", both are very bright compared with the remainder of the known celestial X-ray objects, and both are objects possessing very soft spectra. These findings suggest that *SCO XR-1* and the Crux object are of a similar physical nature. In light of the recent measurement of angular extent and the tentative optical identification of the *SCO XR-1* object<sup>3</sup>, the existence of a second very similar X-ray object becomes a matter of considerable interest.

The initial X-ray detector hardware development was performed at the Southwest Center for Advanced Studies, Dallas, Texas, under an NASA contract. J. R. H. and R. J. F. acknowledge the support provided by CSIRO and Commonwealth postgraduate scholarships respectively. The assistance of the UK Science Research Council in providing the opportunity to make these flights is gratefully acknowledged, as is the help of many kinds provided by the personnel of BAC, Filton,

Fig. 2. Map of the celestial sphere, showing the ground level horizon for each flight and the direction the detector was looking during the scans shown in Fig. 1. The positions of known sources<sup>4</sup>, and the positions of *SCO XR-1* and "CRUX" as derived from these flights, are shown. The position of *SCO XR-1* as given in ref. 3 is obscured by the two UAT points. Note that two UAT points are given for each object, corresponding to the two flights *SL 425/426*.

### Detection of a New Microwave Spectral Line

AFTER the radioastronomical detection<sup>1</sup> of helium in 1966 a programme to study the  $109\alpha$  transition of neutral helium was begun at the US National Radio Astronomy Observatory, and helium has now been detected in five sources (as will be described elsewhere). During the course of this work, however, unidentified microwave spectral emission has also been detected in the sources *NGC 2024* and *IC 1795*. This communication describes the observed physical characteristics of this emission, considers its possible origins and suggests further observations to identify it. In the succeeding communication, Goldberg and Dupree argue that the new line is a recombination line of carbon I.

We worked with the US National Radio Astronomy Observatory 140 ft. telescope, equipped with a cooled parametric amplifier, and the Harvard University twenty-one channel spectral line radiometer. The overall temperature of the system was about 80° K. The observations were carried out at frequencies near those of the  $109\alpha$  recombination lines of hydrogen and helium ( $\sim 5,009$  Mc/s), and at a constant polarization position angle with resolutions of 100 kc/s and 30 kc/s. Figs. 1-3 show portions of the spectra of the sources *NGC 2024* and *IC 1795*. The  $109\alpha$  recombination line of hydrogen is the strong signal on the left in Figs. 1 and 2. In *IC 1795*, there is an unidentified microwave line; on the high frequency side

Fig. 1. Spectrum of *NGC 2024* with 100 kc/s resolution. The ordinate is antenna temperature and the abscissa is frequency relative to the  $H109\alpha$  line in Mc/s. The rest frequency of the  $H109\alpha$  line is 5,008 923 Mc/s. The radial velocity of this line is  $+7.2 \pm 0.4$  km/s. The numbers below the spectrum indicate the expected position of recombination lines of emitters of mass 1, 2, 4, 8, 12  $M_\odot$  and  $\infty$  if they have the same radial velocity as the  $H109\alpha$  line.  $\Delta T_{pp}$  is the peak to peak noise fluctuation.

Fig. 2. Spectrum of *IC 1795* with 100 kc/s resolution. The radial velocity of the hydrogen line is  $-41.8 \pm 0.8$  km/s.

Fig. 3. Spectrum of *NGC 2024* with 30 kc/s resolution. As in Fig. 1, the numbers below the spectrum indicate the expected position of recombination lines of emitters of mass 8, 9, 10, and 12  $M_\odot$ .

of the helium profile. In *NGC 2024* an unidentified line is present, and no helium signal was observed that was significantly outside the noise.

Some characteristics of the unidentified microwave spectral lines are given in Table 1.

Source	Separation from hydrogen (Mc/s)	$v_L$ (km/s)	$T_A$ (°K)	Ratio of area under line profile to area under hydrogen profile
<i>NGC 2024</i>	$2.408 \pm 0.020$	$78^{+20}_{-10}$	$0.10 \pm 0.03$	$3.1 \times 10^{-4}$
<i>IC 1795</i>	$2.49 \pm 0.10$	$< 200$	—	—

In what follows, we shall assume that the unidentified lines have the same origin. If the hydrogen and the unidentified lines have identical radial velocities, the rest frequency of the new line in *NGC 2024* is  $5,011.33 \pm 0.02$  Mc/s. The rest frequency for *IC 1795* is slightly different but within the limits of observational error.

There are several reasons why this new emission line is unlikely to be a recombination line of hydrogen or helium. If, for example, it were a displaced hydrogen  $\alpha$  line, a large peculiar velocity ( $\geq 144$  km/sec) would be necessary to account for it. If it were a displaced helium  $\alpha$  line, the peculiar velocity required would be smaller, but because there is no corresponding feature visible on the hydrogen profile it is unlikely to be helium. If, on the other hand, the new line comes from the same region as the hydrogen  $\alpha$  line, the first higher order transition of hydrogen to lie within the error brackets would be that from  $n = 460$  to  $n = 400$ , and the intensity of that transition would be extremely small. A more decisive consideration is that the observed lines are too narrow to be attributed to hydrogen or helium in H II regions. The width of a Doppler broadened line in the region of about 5,000 Mc/s is

$$\Delta\nu = 358 \sqrt{\frac{T}{10^4} \frac{M_H}{M_S}} + 6.06 \times 10^{-3} V_T^2 \text{ kc/s} \quad (1)$$

where  $T$  is the temperature,  $M_H$  and  $M_S$  are the masses of hydrogen atoms and emitters respectively, and  $V_T$  is the turbulent velocity in km/sec. The observed upper limit to the line width for *NGC 2024* implies a maximum kinetic temperature of  $750^\circ \text{K}$  for hydrogen or  $3,000^\circ \text{K}$  for helium—temperatures which are much lower than those observed for H II regions. It is therefore natural to ask whether the new line can be a recombination line originating from atoms, ions or molecules with mass greater than those of helium.

Recent investigations of the  $137\beta$  hydrogen line in *NGC 2024* by Zuckerman *et al.*<sup>2</sup> have shown that the energy levels responsible for the radio recombination lines are not populated according to local thermodynamic equilibrium. Their results for the  $137\beta$  line imply a kinetic temperature of at least  $8,700^\circ \text{K}$  for *NGC 2024*. With this temperature, equation (1) implies that the mass of the substance emitting the new line is at least  $12 M_H$ , unless there is significant line narrowing by stimulated emission. With  $T = 8,700^\circ \text{K}$  and  $\Delta\nu = 409 \text{ kc/s}$ , equation (1) yields a turbulent velocity for the hydrogen in *NGC 2024* of about  $8.3 \text{ km/sec}$ . The width of the new line in *NGC 2024* is compatible, however, with a turbulent velocity of no more than  $3.5 \text{ km/sec}$ , no matter what the mass or temperature of the emitter may be. The new line may therefore originate from only a part of the H II region. The fact that the emission line was obvious in only two of six H II regions investigated does indeed suggest that rather specialized physical conditions must be satisfied.

If the radial velocities of the source of the new line and of the hydrogen line in *NGC 2024* are the same, the Rydberg formula implies a mass of 8 or  $9 M_H$  for the emitter. Differences of radial velocity no greater than  $5 \text{ km/sec}$  would, however, be consistent with a mass of  $12 M_H$ , corresponding to carbon. The positions of lines from emitters of several different masses are indicated in Figs. 1 and 3. We have examined several effects which would cause deviations from the Rydberg formula for complex atoms, ions, or molecules; they are all small compared with the line width. We note that  $\beta$  lines of doubly ionized emitters,  $\gamma$  lines of triply ionized emitters, and so on, fall at the same positions. A mechanism which may enhance emission lines from heavy atoms or molecules is described in the succeeding communication.

For a firm identification, more observations are needed. The lines in *NGC 2024* and *IC 1795* should be examined with greater frequency resolution in order to determine more accurately the frequency of the line relative to hydrogen and to see whether the line is resolved with  $30 \text{ kc/s}$  filters. To determine if this is a recombination line, we suggest that these observations be carried out at an adjacent transition (either  $108$  or  $110\alpha$ ).

We thank G. Behrens and L. Bowles for assistance in the operation and maintenance of the radiometric system. This work was supported by the US National Science Foundation. The National Radio Astronomy Observatory is operated by Associated Universities, Inc., under contract with the US National Science Foundation.

**Addendum (May 31, 1967).** We have now observed the  $110\alpha$  transition of the new line in *NGC 2024*, thus establishing that it is a recombination line. The observed parameters of the line at  $110\alpha$  are  $T_L = 0.10^\circ \text{K}$ ,  $\Delta\nu = 79 \pm 20 \text{ kc/s}$ , and the ratio of the area under the new line to that under the hydrogen profile was  $3.4 \times 10^{-3}$ , in very close agreement with the values obtained at  $109\alpha$ . The frequency separation of the new line from the hydrogen line was  $2.344 \pm 0.020 \text{ Mc/s}$ , which agrees with the frequency predicted from the  $109\alpha$  observations to an

accuracy of  $6 \text{ kc/s}$ . The observations were again made at the National Radio Astronomy Observatory.

## Population of Atomic Levels by Dielectronic Recombination

IN the preceding communication, Palmer *et al.* have reported the observation of an emission line close to the expected position of the recombination line  $109\alpha$  of C I in the radiofrequency spectra of the ionized hydrogen regions *NGC 2024* and *IC 1795*. The total intensity of the newly observed line is about 3 per cent that of the neighbouring  $109\alpha$  line of H I. Let us assume that the two lines originate from the same volume of space. If the upper levels of C I and H I were populated in thermodynamic equilibrium, the relative intensities of the two lines would be roughly in the ratio of the numbers of hydrogen and carbon ions in the emitting volume. This ratio would be equivalent to that of the cosmic abundances of hydrogen and carbon if both atoms were entirely in the singly ionized condition. In the Sun, the abundance of carbon is  $5 \times 10^{-4}$  of that of hydrogen<sup>1</sup>, and there is no reason to suppose that the ratio is greatly different in H II regions. Thus, if the line found by Palmer *et al.* is indeed the  $109\alpha$  line of C I, its observed intensity relative to that of the same transition in hydrogen is at least sixty times greater than would be expected from the two assumptions of thermodynamic equilibrium and normal cosmic abundances. In this communication we point out that the apparently anomalous overpopulation of the  $n = 110$  level of C I can be explained as a result of departures from thermodynamic equilibrium, which result in the preferential population of levels of high total quantum number by dielectronic recombination.

In a low density plasma exposed to a dilute source of ionizing radiation, the populations of excited levels of atoms are fixed primarily by the balance between electronic recombination and cascade into the levels, and spontaneous transitions out of them. The populations of very high levels are also modified by collisional  $n \rightarrow n \pm 1$  transitions and by collisional ionization and three-body recombination<sup>2</sup>. These processes occur in atoms of all species. There is, however, a crucial difference between the dominant recombination process for a hydrogenic atom and that for a complex ion. The bare nucleus of a hydrogenic ion can recombine only by radiative capture, but an ion that has one or more electrons is able to capture an electron by dielectronic recombination. This process may occur at a much faster rate<sup>3</sup> and with a wholly different dependence on  $n$  and  $l$  than that of radiative capture. Burgess<sup>3</sup> has shown that the dielectronic recombination rate coefficient into level  $i, nl$ , by way of the intermediate doubly excited level  $j, n'l$ , is proportional to  $(2l+1)b(j, nl)$ . Here  $b(j, nl)$  is the factor by which the population of  $j, nl$  differs from its value in thermodynamic equilibrium. The value of  $b$  is given by

$$b(j, nl) = \frac{A_s}{A_s + A_i} \quad (1)$$

where  $A_s$  ( $\text{sec}^{-1}$ ) is the rate coefficient for autoionization from level  $j, nl$ , and  $A_i$  ( $\text{sec}^{-1}$ ) is the rate coefficient of the stabilizing transition,  $j, n'l \rightarrow i, nl$ . When  $A_s \gg A_i$ ,  $b(j, nl) =$

1 and the population has its equilibrium value. In that event the recombination rate coefficient, when summed over all  $l$  values, is proportional to  $n^2$ , whereas the corresponding rate coefficient for radiative capture is proportional to  $n^{-1}$  (ref. 4). Because the rate at which the level  $i, n$  is depopulated by spontaneous emission is approximately the same for hydrogenic and non-hydrogenic ions,  $b(i, n)$  may increase rapidly with increasing  $n$  and may become very large.

This simple picture has to be modified in two respects. First, according to Burgess<sup>3</sup>, the quantity  $b(j, n)$  is unity only for values of  $n$  smaller than about 5–10. Thereafter as  $n$  increases, the autoionization rates and the  $b(j, n)$  values decrease both with increasing  $n$  and, especially, with increasing  $l$ . For example, when  $n = 100$ ,  $b(j, n)$  is effectively zero for all values of  $l$  greater than about 6–10. Second, the populations of levels with very large  $n$  will be modified by collision. In the present context, the most important collisional process is ionization by electron impact and the inverse process of three-body recombination. These processes are certain to arrest the increase of  $b(i, n)$  at some value of  $n$  that is fixed by the electron density, and thereafter to cause it to decrease to unity at the limit when  $n \rightarrow \infty$ .

As an illustration of the points made in the preceding paragraphs, we have made approximate calculations of  $b(4s, n)$  for Ca I in which we assumed that the levels are populated both by dielectronic recombination and cascade and by three-body electronic recombination, and that they are depopulated by spontaneous transitions to lower levels and by ionization by electron impact. We used approximate hydrogenic values for the collisional and radiative cross-sections and carried out the calculations for a temperature of  $10^4$  °K and for two values of the electron density, equal to  $10^3$  and  $10^4$  cm<sup>-3</sup>. The results of the calculations are shown in Fig. 1, in which  $\log b(4s, n)$  is plotted against  $\log n$  for  $n = 10, 20, 50, 100$  and 200, the values of  $n$  for which Burgess<sup>3</sup> has published autoionizing rates in the  $4pnl$  series of calcium. When  $n$  is relatively small,  $b(4s, n)$  increases rapidly with  $n$  until collisional ionization becomes important;  $b(4s, n)$  then passes through a maximum and decreases sharply to

unity at the series limit. The maximum value occurs at  $n = 50$ –100 for  $N_e = 10^4$  cm<sup>-3</sup> and at  $n = 100$ –200 for  $N_e = 10^3$  cm<sup>-3</sup>.

Both the absolute value of  $b(i, n)$  and its rate of change with  $n$  are important in causing the line intensity to deviate from its value in thermodynamic equilibrium. First, the line should appear either in emission or absorption according to the value of both  $db(n)/dn$  and the optical depth of the continuum. Second, the transition rates are proportional to the  $b$ -value of the initial level. Third, to allow for stimulated emission the absorption coefficient in the line must be multiplied by the factor

$$1 - \frac{b(n)}{b(n')} \exp(-h\nu/kT_e) \\ \approx \frac{b(n') - b(n)}{b(n')} + \frac{b(n)}{b(n')} \frac{h\nu}{kT_e} \quad (2)$$

where  $n$  and  $n'$  are the upper and lower levels of the transition, respectively<sup>4</sup>. When  $b(n') > b(n)$ , the factor for stimulated emission is larger than the equilibrium value  $h\nu/kT_e$  and approaches unity in the limit when  $b(n') - b(n) \rightarrow b(n')$ . Conversely, when  $b(n) > b(n')$ , the stimulated emission factor is smaller than the equilibrium value and the emission intensity may be amplified by quasi-maser action.

It would be unwise to regard the preceding calculations as anything but illustrative because they do not include the effects of collisional transitions to and from neighbouring levels, nor do they take account of stimulated emission as a significant factor in populating the levels. Both effects will tend to equalize the  $b(i, n)$  values of adjacent levels and thus to decrease the values of  $db(n)/dn$ . Their introduction is unlikely, however, to alter the principal conclusions reached here, namely: (1) in conditions found in ionized hydrogen regions in the interstellar medium, the capture of electrons by dielectronic recombination can greatly increase the populations of highly excited levels as compared with those occurring in thermodynamic equilibrium; (2) there will be a value of the total quantum number  $n$  for which  $b(i, n)$ , the ratio of the actual population to that in thermodynamic equilibrium, has a maximum value; and (3) recombination lines from complex atoms should be found in emission and, with the appropriate conditions, in absorption.

Returning now to the question of the suspected 109α line of C I in the spectra of IC 1795 and NGC 2024, we have seen that if the carbon is all singly ionized and its abundance relative to hydrogen is the same as that found in the Sun, the observed line intensity requires that  $b(i, 110) \sim 60$ , neglecting stimulated emission. The autoionizing probabilities for the  $j, nl$  levels of C I are not known at present. As a rough first approximation we assume that the  $b(j, nl)$  factors for C I are the same as for Ca I. Our calculations give a value of  $b(i, 100)$  for C I equal to 10 at  $T_e = 10^4$  °K and  $N_e = 10^3$  cm<sup>-3</sup>.

We see that this estimated value is apparently too small by about a factor of six, which, nevertheless, is well within the error of estimation. Furthermore, we have not properly allowed for stimulated emission, although the value  $n = 110$  falls near the maximum of the  $b(i, n)$  versus  $n$  relationship. More exact calculations of the  $b$ 's for C I which are in progress should provide a closer comparison with the observations.

We have also examined the possibility that the carbon line could be formed in an H I region surrounding an H II region. At temperatures of  $10^4$  °K, ordinary radiative recombination<sup>4</sup> proceeds at a much faster rate than dielectronic recombination. The electron density is, however, so low in the H I region<sup>5</sup> that the rate at which the level  $b(i, 100)$  is populated is two orders of magnitude slower than for an H II region. An unreasonably large volume of H I would then be required to produce the observed emission.

Fig. 1. Values of  $b(4s, n)$  of Ca I calculated for an electron density equal to  $10^3$  and  $10^4$  cm<sup>-3</sup>.

Finally, we should ask whether recombination lines of C are more likely to be observed than those of other elements of comparable abundance, such as N I, O I, Mg I and Si I. To provide a rough answer to this question we have calculated for each of these elements the product of the solar abundance  $A_i$  relative to hydrogen<sup>1</sup> and the total dielectronic recombination rate,  $\alpha_i$  (tot) for  $T_e = 10^4$  °K as given by Burgess<sup>7</sup>. The results are given in Table 1.

Table 1. PRODUCT OF THE SOLAR ABUNDANCE RELATIVE TO HYDROGEN AND THE TOTAL DIELECTRONIC RECOMBINATION RATE FOR  $T_e = 10^4$  °K

Atom	$A_i \alpha_i$ (tot)
C I	$1.1 \times 10^{-17}$
N I	$1.8 \times 10^{-18}$
O I	$7.1 \times 10^{-20}$
Mg I	$2.6 \times 10^{-18}$
Si I	$1.7 \times 10^{-17}$
Ca I	$5.8 \times 10^{-17}$

We note that the product appears to be greatest for magnesium and about equally large for calcium, carbon and silicon. The ionization potentials of Ca II, Mg II and Si II, however, are not greatly different from those of H I, being 11.9, 15.0, and 16.3 eV, respectively, whereas for O II the value is 24.4 eV. Thus, of the four elements under consideration, carbon is least likely to be doubly ionized in H II regions. It is noteworthy that the ionization potential of O II is nearly equal to that of He I. Thus the ratio of intensities of the  $\alpha$  lines of O I and He I should be a sensitive indicator of the flux of ultra-violet radiation shortward of 500 Å in the spectra of the exciting stars.

## Abundance of Helium in the Sun

THE observed abundances of elements are largely understood in terms of stellar nucleosynthesis. The origin of helium, however, remains a major problem. Indeed, Hoyle and Tayler<sup>1</sup> concluded that the chief fraction of the helium in the Galaxy was synthesized not in stellar interiors but either in the primordial fireball or in a massive object which preceded the formation of the stars. This communication presents a re-determination of the abundance of helium in the Sun and also reviews determinations of the abundance of helium in other objects.

As is well known, a spectroscopic determination of the abundance of helium in the Sun can be made only with considerable uncertainty. Biswas and Fichtel<sup>2</sup> and also Gaustad<sup>3</sup> have discussed how the abundance of helium can be derived from the combination of the abundance ratios observed in solar cosmic rays and the spectroscopic determination of the abundance for nuclei with the same charge-to-mass ratios as helium.

Revised solar abundances of carbon, nitrogen and oxygen have been obtained from a comprehensive analysis of atomic and molecular spectra (unpublished results). The spectroscopic oxygen abundance is  $\log N_O/N_H =$

$-3.23 \pm 0.05$ , which with the cosmic ray ratio  $N_{He}/N_O = 107 \pm 14$  gives the solar helium abundance as

$$\frac{N_{He}}{N_H} = 0.083 \pm 0.015$$

Furthermore, the abundance ratios given by the spectroscopic analysis

$$N_O/N_O = 0.60 \pm 0.10 \text{ and } N_N/N_O = 0.15 \pm 0.05$$

are in good agreement with the cosmic ray measurements which give<sup>2</sup>

$$N_O/N_O = 0.59 \pm 0.07 \text{ and } N_N/N_O = 0.19 \pm 0.04$$

This agreement provides support for the assumption that the cosmic ray abundances for nuclei with the same charge to mass ratio are equal to the photospheric abundances.

The solar composition expressed in terms of the mass fractions of hydrogen, helium, and the heavy elements is

$$X = 0.79, Y = 0.20 \text{ and } Z = 0.013$$

Previous estimates for the helium abundance, which were based on the same cosmic ray data, gave  $N_{He}/N_H = 0.09$  or  $Y = 0.26$ . The reduction is the result of the downward revision of the spectroscopic determinations of the abundances of carbon, nitrogen and oxygen. Both the previous and present abundances of helium are consistent with recent model calculations for the solar interior<sup>4</sup>.

The composition of the solar photosphere will be assumed to be representative of the interstellar gas at the time of formation of the Sun about  $4.5 \times 10^9$  years ago. A determination of the rate of helium enrichment in the interstellar gas is obtained from a comparison of the helium abundances in the interstellar gas and young stars with the above solar abundance.

Accurate determinations of such abundances are available for gaseous nebulae. Faulkner and Aller<sup>5</sup> find  $N_{He}/N_H = 0.12$  for the Orion and  $\eta$  Carinae nebulae. Determinations of the abundance of helium for O and B stars are reviewed by Underhill<sup>6</sup>. The results are consistent with the gaseous nebulae abundances but are subject to greater uncertainty.

The helium abundance  $N_{He}/N_H = 0.12 \pm 0.02$  is taken to be representative of the present interstellar gas. This abundance exceeds the solar abundance by about a factor of two. The increase over an interval of  $4.5 \times 10^9$  years is attributed to the enrichment of the interstellar gas with helium synthesized in stellar interiors.

The total optical emission of the galaxy can be shown to correspond to the conversion of  $5 \times 10^6 M_\odot$  of hydrogen to helium in this same interval, although the helium abundance in the interstellar gas can be doubled only if the ejection of helium from stellar interiors is about 100 per cent effective. This is a gross overestimate of the likely efficiency. It is therefore necessary to suppose that the helium deposited in the previous  $4.5 \times 10^9$  years was produced before the formation of the Sun when the rate of star formation was markedly greater than at present. This supposition is consistent with Dixon's<sup>7</sup> interpretation of metal deficient stars which shows that the rate of star formation was considerably enhanced for a short period after the collapse phase of the Galaxy. Calculations by Truran, Hansen and Cameron<sup>8</sup> of the increase in the abundances of helium and heavy elements since the formation of the Galaxy provide a certain degree of quantitative support for these ideas. In particular a calculation which corresponds to an exponential decline in the total mass of the interstellar medium with a decay constant of  $3 \times 10^9$  years reproduces the observed solar and interstellar abundances for acceptable ages for the Sun and the Galaxy. Although the observations are consistent with their assumption that the Galaxy was formed from pure hydrogen gas, determinations of helium abundance in very old stars must provide the decisive test.

Unfortunately, observations of helium in old stars are not extensive. Recent discoveries<sup>9,10</sup> of B-type halo stars with an apparently low helium abundance ( $N_{He}/N_H \approx 0.01$ )

are consistent with the prediction. Other observations of similar stars suggest an abundance close to the solar value<sup>11</sup>. A possible explanation is that in such highly evolved stars the surface layers have been contaminated with material from the interior which is rich in helium. Greenstein, Truran and Cameron<sup>12</sup>, however, suggest that the helium deficient atmospheres result from a loss of helium by downward diffusion. The correct interpretation of the helium abundances in old stars must await further observations.

It will be evident that no final conclusion on the origin of helium can be proposed with any certainty. The evidence compiled here suggests that stellar nucleosynthesis of helium was responsible for the increase in the helium abundance in the interstellar gas between the formation of the Sun and the present time. The initial helium abundance for the Galaxy before the formation of stars is uncertain. The upper limit provided by the solar abundance is  $N_{\text{He}}/N_{\text{H}} \leq 0.06$ . This limit is only slightly less than that predicted by recent calculations of helium synthesis in a primordial fireball<sup>13</sup>. The recent discoveries of old stars with an apparently low helium abundance and an extrapolation of the observed rate of helium enrichment suggest that the possibility of a very low initial helium abundance ( $N_{\text{He}}/N_{\text{H}} < 0.01$ ) should be anticipated. The cosmological significance of this result has been emphasized by Hoyle and Taylor<sup>1</sup>.

## Surface Helium Abundance in Horizontal Branch and Halo B Stars

THE surface helium abundance of stars at the blue end of the horizontal branch in globular clusters and of halo B stars has been estimated by spectroscopists to be lower than that at the Sun's surface by factors ranging from 10 (refs. 1 and 2) to 100 (ref. 3). It is assumed that the halo B stars are the field-equivalents of horizontal branch stars, and we hereafter refer to both classes as blue horizontal branch stars.

Greenstein, Truran and Cameron<sup>4</sup> have recently suggested that diffusion in slowly rotating blue horizontal branch stars may be efficient enough to establish a pronounced stratification of elements near the surface, in such a way that the abundance of helium at the photosphere would be considerably smaller than in the interior. Spectroscopic determinations of surface helium abundance, even if they were correct, would then shed no light on what the subsurface abundance might be. Apparent variations would simply reflect differences in the relative efficiency of the diffusion process from one star to the next (whether due to different rates of rotation or surface conditions) and/or differences in the time over which diffusion has been effective in depleting the surface abundance.

Deeming and Walker<sup>5</sup> have shown that, for main sequence O and B stars and for Be stars, the weakness of helium lines is correlated with the narrowness of these lines. Because meridional circulation induced by rotation tends to counter the effects of diffusion inward, these results lend support to the argument that diffusion may have been effective in depleting the abundance of helium at the surface of sharp-lined blue horizontal branch stars.

In this communication we prefer to use the term depletion mechanism when discussing the observations, because gravitational diffusion is not the only effect which could cause a separation of elements (resonance radiation absorption<sup>6</sup> is another possibility). We wish to point out that if the helium deficiency factor ( $\sim 100$ ) given by Sargent and Searle<sup>9</sup> is correct, it is a clear indication that some mechanism is effective in depleting the surface abundance. On the other hand, the estimates given by Searle and Rodgers<sup>1</sup> and Greenstein and Münch<sup>10</sup> do not allow one to come to this same conclusion. In the latter cases, we shall show that a deficiency factor of  $\sim 10$  could be consistent with the assumptions that globular cluster stars began life with a vanishingly small helium content and that no effective depletion mechanism has been operating.

Our argument is based on investigations of stars evolving from the main sequence to the red giant tip, that is, the progenitors of horizontal branch stars. The helium content to assign to the precursors themselves is, of course, related to the point in question. We have recently computed models (ref. 7 and unpublished results) for globular cluster stars of low metal content,  $Z/Z_{\odot} \approx 1/100$ , and for values of the initial helium content (a)  $Y = 0.35$ , (b)  $Y = 0.10$  and (c)  $Y = 0.00$ . Such values span the probably acceptable range. The appropriate masses to obtain satisfactory agreement with the main-sequence turn-offs are (a)  $M/M_{\odot} = 0.65-0.75$ , (b)  $M/M_{\odot} = 1.0-1.2$ , and (c)  $M/M_{\odot} = 1.2-1.4$ .

During the long main sequence phase which precedes the climb up the giant branch, these models have relatively low central temperatures and rely essentially on the pp chain for their energy generation. As a result, an extended profile of helium content versus mass fraction is built up. As the models climb up the steep part of the giant branch, the base of a growing convective envelope extends into the interior, where it is eventually forced to retreat again in front of the advancing hydrogen burning shell. While the envelope grows, convective mixing progressively increases the abundance of helium at the surface; this reaches a maximum when the envelope is at its largest extent. Whereas the models leave the main sequence when a helium core of a certain fractional mass has been attained, the structure and position on the giant branch are determined by the actual core mass. For the massive models, helium has been produced much further out as a function of actual mass. Thus, for these models, more helium is available for potential mixing to the surface. Our results for the total helium enrichment ( $^3\text{He} + ^4\text{He}$ ) of the surface are (a)  $\Delta Y \leq 0.005$ , (b)  $\Delta Y \approx 0.015-0.018$ , and (c)  $\Delta Y \approx 0.024-0.027$ . From these figures it is clear that the enrichment figure for stars of type (c) represents the lowest envelope helium content with which stars can arrive at the red-giant tip.

As an aside, it is of interest to note the region over which the change in surface composition occurs,  $1.0 \leq \log L/L_{\odot} \leq 1.7$ . Thus the change is confined to a region somewhat less than two magnitudes in extent, and ceases at a luminosity in the neighbourhood of horizontal branch luminosities<sup>8,9</sup>. There may be evidence for this in the recent results of Sandage and Walker<sup>8</sup> in M92, where an anomalous colour effect is thought to be operating in precisely the same region. Sandage and Walker reached the conclusion that if a difference in chemical composition were required to explain the difference in the ultra-violet colours for stars of a given B-V on the giant

branch and horizontal branch, the difference would have to act along the giant branch itself. The principal surface changes to be expected from our work will be among the light elements, up to carbon and nitrogen. Although the sum of the abundances of carbon-12 and nitrogen-14 remains constant along the giant branch, the ratio of nitrogen-14 : carbon-12 is increased by about a factor of three. The increase occurs as a result of convective mixing with interior regions where carbon-12 has been converted into nitrogen-14 during the main sequence phase (see, for example, ref. 10). Although it is difficult to see how burning, or a mere shuffling among the light elements, can have the desired effect, we nevertheless feel that there may well be a connexion between this observation and our results.

Returning to the giant branch, we have shown that the convective envelope attains a helium content with lower bound  $\sim 0.1 Y_{\odot}$ , where the solar value,  $Y_{\odot} \sim 0.27$  (for example, ref. 11). It is generally accepted (E. A. Spiegel, personal communication) that the convective envelope extends virtually to the photosphere, and that overshooting will certainly mix the photosphere to the same composition. Even were this not the case, models of type (b) and (c) must lose considerable mass in order to populate the horizontal branch<sup>7,8</sup> and thus the layers which become the horizontal branch photosphere must have been inside the giant convective envelope. If the mass loss occurs sufficiently late on the giant branch, the helium enrichment will be essentially that given above. If, however, mass loss were to occur earlier, before helium enrichment has attained its maximum value, then the figure could be increased. This conclusion is reached from inspecting our models where, within each class, the base of the envelope is deeper for the models of lower total mass. Thus, by comparison with a model of constant mass, more helium is scoured out, to be diluted by less hydrogen.

In order to test the sensitivity of these results to the convection theory of the outer layers, some models were run for two choices of the ratio of mixing-length to scale-height, 0.5 and 1. While the surface temperature is sensitive to the change, conditions deep inside the models remain the same, and the helium enrichment figure is virtually unaffected.

The final conclusion, therefore, is that blue horizontal branch stars should contain, before the operation of any depletion mechanism, at least  $\sim 0.1 Y_{\odot}$  in their photospheres. Sargent has asserted (personal communication) that the deficiency factor for the stars observed with Searle is undoubtedly greater than fifty. It thus seems clear that we have here a *reductio ad absurdum*, and that a depletion mechanism must have operated. This being the case, there would be no reason from spectroscopy to prefer any particular value for the initial helium content, and observations of horizontal branch stars could not be used to argue against any picture of the synthesis of primordial elements.

If, on the other hand, the Sargent and Searle observation is not confirmed, the other existing observations<sup>1,2</sup> would be consistent with (i) no helium initially, and no effective depletion, (ii) "solar-like" helium initially, and depletion by a factor of ten or (iii) some combination of (i) and (ii). According to the choice of initial helium content, stars arrive at the blue end of the horizontal branch either (i) directly, and evolve away to the red in  $2-4 \times 10^7$  years (low helium) or (ii) after evolving from the red end for  $\sim 10^8$  years (high helium)<sup>1</sup>. These results may then be combined with the observations to yield an indication of the time scales over which, on the various hypotheses, depletion may or may not have been effective. Unfortunately, the results are not unambiguous. It becomes important to determine theoretically the final steady state distribution of elements near the photosphere, if diffusion is indeed operative. Such a question, however, lies outside the scope of the present communication.

## PLANETARY SCIENCE

### Evidence for Velocity Dispersion in Auroral Electrons

The intensities of 10 keV and 4 keV electrons have been measured from a sounding rocket launched into a post-breakup aurora. Pulsations in electron intensity were observed with a period of about 4 sec at both energies. The 10 keV pulsations occurred about half a second earlier than those at 4 keV. These results could have been caused by temporal changes in electron intensity and by a spatial structure in the path of the rocket because the causes are indistinguishable in the data. We treat the observed pulsations as temporal changes; they are similar in shape to pulsations observed in auroral light intensity, and electrons in the range 10 keV to 4 keV are important in the production of auroral light. If the pulsations are temporal in origin, the delay can be explained as a dispersion after simultaneous modulation 55,000 km from the rocket. The source of the modulation is found to be near the point where the local magnetic field line crosses the geomagnetic equator.

The measurements were made from a Nike-Apache rocket launched from Andoya in Norway at 2358 h U.T. on March 3, 1967. The flight was made during the recovery phase of a magnetic bay recorded at the Auroral Observatory at Tromsø, 120 km from the launch site. The magnetogram is shown in Fig. 1. Heppner<sup>1</sup> and

Fig. 1. Horizontal component of Earth's magnetic field measured at Tromsø, 120 km from the launch site at Andoya. The rocket was launched (arrow) 2358 h U.T. March 3, 1967. The measurements reported in this paper were taken near apogee at about 0002 h U.T. March 4, 1967. The vertical scale is given in units of  $\gamma$ , where  $1\gamma = 10^{-4}$  gauss. The magnetogram is reproduced by courtesy of the Director of the Tromsø Auroral Observatory.

Fig. 2. Counting rates of the 4 keV (top) and 10 keV (bottom) electron detectors taken near apogee. The pulsations in electron intensity labelled A to D are discussed in the text.

Crosswell and Davis<sup>3</sup> have found that pulsating aurorae are seen most frequently at this phase of a magnetic storm. The electron detectors were channel multipliers used in conjunction with cylindrical electrostatic analysers. Two analysers selected electrons in narrow bands of energy near 10 keV and 4 keV. A third analyser with no electric field between the cylindrical plates served as a control. The measurements reported here were taken during a period of 40 sec while the rocket was near its apogee of 195 km.

Fig. 2 shows the counting rates of the 10 keV and 4 keV detectors plotted against time. The rates are represented by error bars ( $\pm$  one standard deviation) drawn through points obtained from successive rocket spin periods of 0.13 sec. The control measurement showed that the background rate was always less than 1 per cent of the rate recorded by the other detectors. In the 10 keV record (Fig. 2) a period of relatively low intensity is followed by a series of pulsations labelled A to D. The pulsations stop with the intensity at about the highest level recorded during the pulsations. These features are similar to variations in light intensity observed by Johansen and Omholt<sup>4</sup> during pulsating aurorae. The 4 keV intensity variations are similar in form but less clearly defined because the changes in intensity are smaller and the counting rates are lower. The pulsations occur about 0.5 sec earlier at 10 keV than at 4 keV. It is clear from the characteristic shapes of the pulsations that the delay does not differ from 0.5 sec by an integral number of pulsation periods. The difference in timing is illustrated in Fig. 3 in which five-point running means of the 10 keV

Fig. 3. Running means of the 10 keV (---) and 4 keV (—) counting rates for the pulsations A to D. The superimposed curves show that the pulsations at 10 keV occurred earlier than those at 4 keV.

and 4 keV counting rates are superimposed. Both records are normalized to an average value of zero in the 6 sec period before the pulsations, and an average value of 100 in the 6 sec period after the pulsations. Although there are differences in detail, the general features of the two records are similar with the 10 keV pulsations occurring consistently earlier than the 4 keV pulsations. A quantitative measure of the difference in timing was obtained by dividing the data of Fig. 2 into seven sections corresponding to the principal changes in counting rate, and cross correlating the data with relative delays incrementing by 0.13 sec the rocket spin period. On combining the results to obtain an average delay,  $\Delta t$ , between the 10 keV and 4 keV pulsations we obtain

$$\Delta t = 0.55 \pm 0.1 \text{ sec}$$

To find the distance of the source of the pulsations we assume that the

10 keV and 4 keV electrons were modulated simultaneously, and that their subsequent motion was adiabatic. The distance,  $s$ , between the source and the point of observation measured along the electron trajectory is then given by

$$s = \frac{V_1 V_2}{(V_1 - V_2)} \cdot \Delta t$$

where  $V_1$  is the speed of a 10 keV electron and  $V_2$  is the speed of a 4 keV electron. Substituting for  $V_1$ ,  $V_2$  and  $\Delta t$ , we find

$$s = (5.5 \pm 1.0) \times 10^4 \text{ km} \quad (1)$$

In principle the source of the pulsations can be located by tracing the electron trajectory at a distance  $s$  along the local geomagnetic field line. The flight was made at a local geomagnetic time of 0320 h during a magnetic bay on the magnetic shell  $L = 6$ . Beyond a few Earth radii this shell is distorted from the dipole form by inflation of the magnetosphere. The source, however, may be located approximately by computing electron trajectories in a dipole magnetic field. Using the value of  $s$  given in equation (1), and taking account of the range of pitch angles viewed by the detectors during each rocket spin period, we find the geomagnetic latitude,  $\theta$ , of the source to be

$$\theta = 7^\circ \text{ south} \pm 13^\circ$$

We see that an interpretation of the data based on some simplifying assumptions leads to the conclusion that electrons responsible for the production of the aurora can be significantly affected by processes occurring as far from the aurora as 55,000 km. The implication of this result is that the route taken by the auroral electrons passes close to the geomagnetic equator at a distance of six Earth radii.

We thank the Norwegian Defence Research Establishment for the opportunity to participate in their auroral rocket programme. The generous co-operation of Dr Landmark and his group is particularly appreciated.

## Joint Epicentre Determination

THIS communication describes a method of determining station travel time corrections and the positions and origin times of more than one earthquake simultaneously. Application of the method to earthquakes from the same region should reveal any regional bias in travel times. Some preliminary results are presented.

Suppose the rough epicentre, depth and origin time of a seismic event are known, the equation of condition for calculating the corrections to these approximate values is<sup>1</sup>

$$\delta H + \delta h \frac{\partial T}{\partial h} + x \cos \alpha_j \frac{\partial T}{\partial \Delta_j} - y \sin \alpha_j \frac{\partial T}{\partial \Delta_j} = \delta T_j \quad (1)$$

where  $\delta T_j = A_j - H - T_j$ ;  $H$  is the approximate origin time of the event;  $h$  is the approximate depth of the event;  $\Delta_j$  is the distance from the approximate epicentre to station  $j$ ;  $\alpha_j$  is the azimuth from the approximate epicentre to station  $j$ ;  $A_j$  is the time of arrival (of the  $P$  waves) at station  $j$ ;  $T_j$  is the travel time (of the  $P$  waves) from the approximate epicentre to station  $j$ ;  $\partial T/\partial \Delta_j$  is the partial derivative of the travel time  $T (= f(\Delta_j, h))$  with respect to distance at the point  $\Delta_j, h$ ;  $\partial T/\partial h$  is the partial derivative of the travel time  $T$  with respect to depth at  $\Delta_j, h$ ;  $T$ ,  $\partial T/\partial \Delta_j$ , and  $\partial T/\partial h$  are obtained from travel time tables.

The unknowns  $x$ ,  $y$ ,  $\delta h$  and  $\delta H$ , the corrections to latitude, longitude, depth and origin time respectively, can be estimated by the method of least squares from equation (1) provided  $j > 4$ . A more accurate estimate of epicentre, depth and origin time can thus be obtained. Further corrections to this new epicentre can be calculated in the same way and the process repeated calculating successively better approximations to the (least squares) estimates of the epicentre parameters until the corrections become small enough to neglect. Convergence towards the best estimates is usually rapid.

Recent work (for example, ref. 2) has shown that equation 1 should include a term for the station correction  $S_j$ , where  $S_j$  is the difference between the observed travel time and the travel time obtained from the travel time tables. The results of several special studies have been published giving estimates of station corrections.

When these station corrections are available they can be applied to the arrival times  $A_j$  and these corrected times substituted in equation 1. The epicentre calculation can then proceed as before.

Cleary and Hales<sup>3</sup> have also shown that some station corrections are dependent on azimuth, and Herrin and Taggart<sup>4</sup> and Helterbran and Jordan<sup>5</sup> report that, at least from the LONGSHOT area, travel times vary azimuthally. Corrections for the azimuthal variations should therefore also be applied if accurate epicentres are to be estimated. But these corrections, particularly the source bias, are difficult to detect, because the usual method of estimating epicentres, by definition, shifts the position of the event until the residuals show no bias. Some of the bias can, however, be detected by estimating simultaneously the station corrections and epicentres of several events from the same region.

Equation 1 can be rewritten to include the station corrections  $S_j$ ;  $S_j$  contains the travel time bias as well as the station effect. Thus if  $\delta S_j$  is the correction to the approximate value of  $S_j$ , equation 1 becomes for the station  $j$  recording the  $i$ th event

$$\delta S_j + \delta H_i + \delta h_i \frac{\partial T}{\partial h_i} + x_i \cos \alpha_{ij} \frac{\partial T}{\partial \Delta_{ij}} - y_i \sin \alpha_{ij} \frac{\partial T}{\partial \Delta_{ij}} = \delta T_{ij} \quad (2)$$

where  $\delta T_{ij} = A_{ij} - H_i - T_{ij} - S_j$ .

As equation 2 stands,  $\delta S_j$  and  $\delta H_i$  are linearly dependent and equation 2 cannot be used to estimate the unknowns. This difficulty can be overcome by assigning a value to one  $S_j$  or, what is probably better, by assuming

that  $\sum_j S_j = 0$ , that is, it is assumed that the mean station correction is zero. With this assumption the epicentre, depth, origin time and station corrections can be estimated—at least in theory.

A computer programme has been written for joint epicentre and station correction estimation, based on equation 2. Preliminary tests using seven events from the Aleutian Islands recorded at some or all of thirty stations (each station recorded at least two events) show rapid convergence (computed corrections are usually  $< 0.01$  after three or four iterations) if the depth of at least one event is held fixed (restrained). With no depth restraints convergence is slow and the estimates tend to oscillate.

The events used include the LONGSHOT explosion: the normal method of epicentre determination gives estimates 25–30 km north of the true epicentre. The method of joint epicentre determination should give a more accurate estimate; LONGSHOT is therefore a valuable datum against which to test the joint epicentre method.

To obtain the results shown in Tables 1 and 2 all events have had their depth restrained to the depth estimated by the US Coast and Geodetic Survey; the event of October 29, 1965, LONGSHOT, has been restrained to 0 km. The arrival times used for these calculations are taken from the *Earthquake Data Reports* published by the US Coast and Geodetic Survey. The stations used have been chosen to cover as many azimuths as possible: all stations closer than  $15^\circ$  to any of the epicentres have been excluded from the analysis as have all stations for which the residuals after convergence were greater than 3 sec (the epicentres were recalculated with the stations with residuals greater than 3 sec removed).

Table 1 shows for each of the seven events: (1) the US Coast and Geodetic Survey epicentres (the LONGSHOT epicentre is the true epicentre), (2) the epicentre determined by the standard method using only those stations used in the joint determinations and (3) the results of the joint epicentre determination; Table 2 shows the station corrections. It is clear from Table 1 that the joint epicentre method gives a much closer estimate ( $\approx 1$  km) to the true LONGSHOT epicentre than the normal method ( $\approx 23$  km).

The error in the LONGSHOT epicentre as determined by the standard method is caused by a regional bias in travel time in the Aleutian region. This bias can be seen in the LONGSHOT residuals—the difference between the observed travel times and J-B travel times from the true LONGSHOT epicentre (Table 2)—superimposed on a base-line shift of about -3 sec. The station corrections (Table 2) computed by considering seven Aleutian events together reveal a similar bias (but not of course the base-line shift which is taken up in adjustments to the origin time): stations to the south of the Aleutian Islands show generally positive station corrections; those to the north show generally negative corrections. The joint epicentre method takes account of the bias.

Thus in a region of known bias the method of joint epicentre determination has detected the bias and produced a more accurate estimate for a (known) explosion epicentre than can be obtained by the normal method. To do this the depths of all the events were assumed to be known. Errors in these assumed depths will tend to bias the epicentral estimates but this bias is probably small. The accuracy of the estimates of the LONGSHOT epicentre suggests either that the estimates of depth are accurate or, more probably, that only gross errors in depth have any appreciable effect on the epicentral estimates.

The joint epicentre method as outlined here breaks down if all the events used are close together—that is, if they are spread over only a few degrees of arc—because the station corrections and travel times are virtually linearly dependent. The method can, however, be adapted to obtain the relative positions of a group of closely spaced events by restraining the epicentre and time of origin of one of the events; the station corrections are then the only unknowns in the equations of condition of the restrained event. If the absolute position of the reference event is known or can be estimated by considering the reference event as one of a group of more widely spaced events—as illustrated here for the seven Aleutian Island events—epicentres determined relative to the reference event will be estimates of the absolute epicentres. A detailed picture of events on both the local and regional scale can therefore be built up. (In theory all events from a given area could be considered at once; in practice the number of events that can be considered at any one time is limited by the storage capacity of the computer available.)

More tests are required to prove the method of joint epicentre determination and work is continuing, particularly to study the value of the method for focal depth

estimation and to calculate the confidence limits on the estimates. This communication simply draws attention to the method.

## Pulsating Radio Auroral Echoes

PULSATING auroral echoes have been described<sup>1</sup> which accompany sudden commencements, and attention has been directed to the fact that the periods of repetition of these echoes are close to those predicted for the bounce periods of hydromagnetic waves along the geomagnetic line of force terminating in the echo region. More exactly, the bounce periods considered are those for waves having angular frequencies  $\omega$  which are considerably less than  $\Omega_e$ , the minimum (equatorial plane) particle cyclotron frequency along the field line. Thus there can be an apparent agreement between echo period and hydromagnetic bounce period for  $\omega \approx 0$  up to  $\omega \approx 0.1 \Omega_e$ , beyond which the travel time increases as  $\omega \rightarrow \Omega_e$ .

Other workers<sup>2-4</sup> have tried to relate periodicities in absorption and X-ray measurements to low frequency standing-wave oscillations of the magnetic field lines and it has been suggested that the particle beam giving rise to these effects is modulated by large-scale variations in the value of the magnetospheric magnetic field. If the interpretations in ref. 1 are correct, particularly where the special event of July 15, 1959, is concerned, then the mechanism just described would be of too large a scale perpendicular to the field lines to allow the resolution in range which is obtained.

Another possibility considered here is that the pulsations arise from a resonant interaction of the type discussed by Wentzel<sup>5</sup>, and, because we require periodicities related to hydromagnetic bounce periods, we are restricted to particle beams capable of interacting with left-hand polarized waves for which  $\omega > \Omega_{ci}$ , where  $\Omega_{ci}$  is the minimum proton gyrofrequency on the path. The conditions for resonance are<sup>6</sup>

$$\left| \frac{\Omega}{\omega} \right| = \left| \frac{V_z}{U} \right| + 1 \quad (1)$$

for particles and waves of similar polarization but opposite directions along the field;

$$\left| \frac{\Omega}{\omega} \right| = \left| \frac{V_z}{U} \right| - 1 \quad (2)$$

Fig. 1 Event on 8-5-60, 0421 U.T., showing fine structure in an echo pulse. (Radar operating on two beams.)

for opposite polarisations but with the same direction of travel.

Here  $V_z$  and  $U$  are the velocities in the field direction of particles and waves, respectively.

The equatorial plane region of the field line having  $L = 4$  is considered so that for protons and electrons on the model we used we have  $\Omega_{e1} = 45$  and  $\Omega_{e2} = 8 \times 10^4$  rad/sec, respectively. For a proton beam with  $\omega = 0.1 \Omega_{e1}$  and  $U = 3 \times 10^7$  cm/sec the required energy parallel to the field is 50 keV. An electron capable of interacting with the same wave would have to have an energy of several MeV. Inspection of one of the auroral echo examples (Fig. 1) suggests, in fact, that the beam may be composed of protons because one of the echoes has a fine structure period of 24 sec, corresponding to a proton energy of 150 keV (for a proton mirroring at low altitude).

The hydromagnetic wave frequency involved is 0.7 c/s and micropulsations of this frequency have been reported<sup>7</sup> after sudden commencements. Trains of pulsations were, in fact, observed with repetition periods of about 2 min for the trains. These observations can explain at least qualitatively the occurrence of pulsating auroral echoes (Fig. 2).

Fig. 2. Conditions under which precipitation may occur at B if a proton resonates with a wave near A.

If the resonance condition can be satisfied near A for a wave coming from B, and a proton going towards B, then the proton may be trapped<sup>8,9</sup> in the wave for at least part of its journey along the field line. Because of the resonance condition, and the fact that  $\Omega$  and  $U$  increase from A to B, it may then be accelerated along the field. If it leaves the wave or falls away from the resonance condition somewhere between A and B with a small enough pitch angle it will be precipitated. It is known<sup>8</sup> that the energy of a particle subject to trapping in a uniform steady field  $B_0$  will vary with a certain period  $T$ . If the particle is to remain trapped when  $B_0$  varies with distance, then the variation of  $B_0$  (and  $\Omega$ ) in one period  $T$  should be small<sup>8</sup>. A proton for which the low initial energy approximation<sup>8</sup> holds, putting  $B_0 = 455\gamma$ ,  $B = 1\gamma$  (wave amplitude) and  $\Omega_{e1} = 45$  rad/sec, would have a period of 8.4 sec. A velocity of  $3 \times 10^8$  cm/sec parallel to  $B_0$  has been assumed and it can be seen that in this case  $B_0$  varies too rapidly to allow trapping. Precipitation may still occur, however, as a result of the impulse given to the particle during its passage through the wave in the equatorial plane resonance region. In a frame of reference fixed to the wave<sup>8</sup>,

$$V'_z = -\beta V_0 \cos p$$

where  $\beta = eB/mc$ ,  $B$  is the wave amplitude, subscript 0 refers to the direction perpendicular to  $B_0$ ,  $p = (k \cdot \vec{V}_z - \Omega) t$ , and  $k$  is the hydromagnetic wave number.

The maximum value of the acceleration in the  $z$  direction is  $3 \times 10^8$  cm/sec<sup>2</sup> taking  $V_0$  as  $3 \times 10^7$  cm/sec and  $B$  as  $1\gamma$ . If  $p$  is initially zero and changes mainly because of the variation of  $\Omega$  with  $z$ , which will be the case if  $V_z$  is  $3 \times 10^8$  cm/sec as above ( $\Omega \approx \Omega_{e1} + bz^2$ , say near the equatorial plane), then  $p$  increases to  $\pi/2$  in about 1 sec because  $b = 2.6 \times 10^{-17}$  rad/cm<sup>2</sup>/sec for  $L = 4$ .

The change of pitch angle in traversing the whole wave can be estimated from

$$\alpha' = -\frac{V'_z}{V_0} = \beta \cos p \quad (3)$$

which neglects any change in  $\alpha$  due to  $dB_0/dz$ , except where this is involved in  $p$ . This time putting  $\Omega_1 = \Omega_{e1} + b'z$ , and integrating equation 3 gives, assuming the  $V_z$  variation is small compared with the  $\Omega_1$  variation,

$$\begin{aligned} \delta\alpha &= \beta \int_{-\infty}^{\infty} \cos b' V_z t^2 dt \\ &\approx \beta \int_0^{\infty} \cos b' V_z t^2 dt \\ &= \frac{\beta}{2} \sqrt{\left( \frac{\pi}{2 V_z b'} \right)} \end{aligned}$$

Again with  $B = 1\gamma$ ,  $V_z = 3 \times 10^8$  cm/sec and  $b' = 1.5 \times 10^{-8}$  rad/sec/cm,  $\delta\alpha$  is of order  $1^\circ$ . This probably underestimates  $\delta\alpha$  since if the proton encounters the wave on both sides of the resonance region we can double  $\delta\alpha$  and also the value of  $b'$  in the resonance region has been overestimated because it has been assumed that  $\Omega_1$  varies linearly with distance.

Thus for protons already mirroring at relatively low altitudes (for the foregoing example, the initial  $\alpha$  is  $5.7^\circ$ ) significant changes in pitch angle can occur. These may be enough to cause precipitation after only one traverse of the wave train provided that the wave amplitude is about  $1\gamma$  or greater and the proton has the correct phase  $p$  in the resonance region.

The radar echoes<sup>1</sup> are generally confined to the range interval from 400 to 1,200 km which involves that part of the magnetosphere between  $L = 3$  and  $L = 4.5$ . To explain the observed echo "dispersion" in time against range<sup>1</sup> we need only invoke the differing travel times of a particular wave frequency along different field lines. Thus it is suggested that at some stage during the sudden commencement, a particular hydromagnetic wave frequency appears on field lines in the region mentioned previously with, possibly, a delay not greater than a minute between its occurrence at small  $L$  and later at larger  $L$  values. An echo pulse will appear if the wave (or waves) is moving in the correct direction and there may be a small "dispersion" in range. Later pulses would appear each time the wave crossed the equatorial plane in the correct direction and because of the varying travel times the "dispersion" would increase. Without knowing the wave frequencies involved in actual events it is not possible to say how much the "dispersion" is influenced by  $\omega$  approaching  $\Omega_{e1}$ . The few examples studied so far suggest that  $\omega$  is not much greater than one-tenth of the minimum proton gyro frequency in the region  $L = 3$  to  $L = 4.5$ .

Current theories of micropulsations<sup>10</sup> suggest that the precipitating wave may be generated or amplified by protons with velocities parallel to  $B_0$  similar to those considered here but with large pitch angles in the equatorial plane.

This hydromagnetic mechanism appears to explain satisfactorily the production of pulsating auroral echoes, but it cannot account directly for the pulsating electron precipitation (with energies in the region of 100 keV) observed during commencements<sup>8</sup>. It is possible, how-

ever, that these electrons are accelerated into the atmosphere by a space charge electric field set up when positive charge in the form of protons is removed from the magnetosphere.

## THE SOLID STATE

### Formation of Voids in Creep and Competition from Sintering Processes

IN the mode of fracture at elevated temperatures and low stresses which involves the nucleation and growth of voids on grain boundaries<sup>1</sup>, the initial stage of formation of the voids is generally considered to depend on a mechanism whereby close competition takes place between the rate of separation of interfaces and the simultaneous tendency to closure by sintering processes. If a void can be opened to a critical size, which depends on the stress and surface tension of the material, then its continued growth can be accounted for by vacancy condensation<sup>2</sup>, but there is little information about the important parameters which may govern conditions before this stage is reached. Proposed mechanisms for void nucleation usually envisage that the most favourable circumstances for nucleation arise when the deformation, particularly the contribution due to grain boundary sliding, is rapid. In such cases it is often considered the void has a higher probability of opening sufficiently before a competing sintering process can be effective in preventing the critical size being reached<sup>3</sup>. This letter presents initial results on experiments with the specific aim of determining the variation of nucleation rate with the rate of deformation.

In the experiments, tensile stresses between 415 and 1,400 lb./in.<sup>2</sup> (derived from weights acting on a cam which reduced the force on the specimen in proportion to the reduction in area) were applied to magnesium specimens of grain size 0.4 mm and having principal impurities in p.p.m. by weight as follows: iron 20, hydrogen 15, manganese 15, nitrogen 20, tin 10, zinc 35. The resulting creep rates of the specimens ranged from 10<sup>-3</sup> to 10<sup>-2</sup>/h at 300° C. An important additional feature was that the tests were made inside a pressure vessel containing argon at pressures between 15 and 1,000 lb./in.<sup>2</sup>, the value for each test being such that the resultant tensile stress component in the specimens was always kept at the same value of 400 lb./in.<sup>2</sup>. Under these conditions it is known that there is a constant driving force for void growth by the condensation of vacancies which diffuse from grain boundaries which is independent of the creep rate<sup>4,5</sup>. Because of this maintaining constant of the process which governed the growth of voids above a critical size, it was possible to investigate the dependence of void nucleation on deformation rate without the usual complicating conditions of different void growth rates.

Changes in the density of specimens were measured at varying stages of creep and the specimens were examined metallographically to determine the number of voids present after given conditions of test. Both these methods indicated that the number of voids was approximately

proportional to the total creep strain and that void nucleation was not strongly sensitive to the rate of deformation. It is implied from this that competing sintering processes are ineffective<sup>6</sup> or that voids are created as a result of deformation at a size sufficiently great for subsequent vacancy condensation under the applied stress and that the time must be short for voids to reach this critical size. Furthermore, there would seem to be no evidence that diffusion processes compete seriously in tending to close the voids and prevent their reaching this critical size over a wide range of strain rates where cavitation is prevalent.

If these results are assumed to be more widely applicable than in the context of the present work, then they make it possible to account for some of the principal features of creep cavitation phenomena which have been generally observed. In particular, the results substantiate the rather common feature that for a given material the elongation to fracture without superimposed hydrostatic pressure in the range where cavitation occurs is not strongly sensitive to the test conditions<sup>7</sup>. By considering that cavities are nucleated progressively with strain and by a mechanism which is not strongly sensitive to strain rate, it is possible to develop a more quantitative approach in interpreting the cavitation process.

A full account of this work will be published elsewhere.

## BIOPHYSICS

### Decrease in Hydrothermal Stability of Collagen on Ageing in the Human Intervertebral Disk

THE shrinkage temperature of the collagen of dura mater or fascia lata has been shown to increase with age<sup>1</sup>. Shrinkage of these tissues and tendon or skin can be watched and a micro-melting point apparatus was used for their determinations. The transition can also be detected from force-temperature curves, and use of this method has shown an increase of shrinkage temperature with age for tendon collagen, except when measurements were made at pH less than 4.5. If the fibres were maintained at constant length during the heating, the shrinkage temperature showed little variation with age (or pH)<sup>2-4</sup>.

It has been claimed that measurements of the tension developed by collagen fibres during heating, the weight required to inhibit contraction and the amount of hydroxyproline or total material dissolved are more sensitive criteria than the shrinkage temperature for assessing changes in hydrothermal stability<sup>5,6</sup>. Unfortunately, the first two methods are difficult to apply to collagen which is not well orientated, as in the nucleus pulposus, the gel-like central portion of the intervertebral disk. Hallén<sup>7</sup> could not detect shrinkage of this tissue under the microscope and we also found difficulty, especially with old specimens. Differential thermal analysis<sup>8</sup> offered a more sensitive means of detecting the transition, and the technique has been applied in our

laboratories in investigations of the nucleus pulposus and the surrounding annulus fibrosus of human disks<sup>8</sup>.

Samples of specimens obtained at autopsy were soaked overnight in water at 2° C. Differential thermal analysis was carried out on the aqueous suspensions using a Dupont 900 analyser and glass beads as reference material. Thermograms were recorded with a  $\Delta T$  scale of 0.1° C/in. for maximum sensitivity and results obtained using heating rates of 5° and 10° C/min were compared. The greater heating rate usually gave larger peaks, at a somewhat greater temperature (curves 2 and 3 in Fig. 1), and so it was used in the age investigation. The nucleus pulposus generally gave broader peaks than those obtained with the annulus fibrosus, but before the age of about 65 they were fairly well defined and there was little difficulty in measuring the parameters shown in Fig. 1. At greater ages an endothermic change was almost impossible to detect in most thermograms of the nucleus pulposus, but a definite increase in the base line slope was often observed, indicating that a small transition had occurred (curve 5 in Fig. 1). A few of the oldest specimens of the annulus fibrosus gave similar results.

The values obtained for the extrapolated onset temperature,  $T_1$  (Fig. 1), for specimens of different ages are given in Figs. 2 and 3 and also regression curves corresponding to quadratic equations, which seemed to fit the data better than linear regression lines, especially for the nucleus pulposus. A statistical comparison was also made of the various age groups indicated by horizontal lines in Figs. 2 and 3. A very significant difference (0.1 per cent level) was found between the 0-10 yr group mean of the nucleus pulposus and the mean of any other group of that tissue. This was also true of the annulus fibrosus except for the 30-40 yr group, but this was significantly lower than the 0-10 yr mean at the 1 per cent level. Significant differences were also found between the 30-40 and 61-71 yr group of the nucleus pulposus (2 per cent level) and between these age groups of the annulus fibrosus (1 per cent level). There was no doubt, therefore, that  $T_1$  of both tissues tended to decrease with age, up to the sixth decade at least, and the other parameters,  $T_2$ ,  $T_3$  and  $T_4$  (Fig. 1), showed a similar decrease. The regression curves, however, indicated a marked reduction in  $T_1$  of the nucleus pulposus during the first 3 or 4 decades, followed by a more gradual change, whereas  $T_1$  of the annulus fibrosus decreased almost linearly for the whole age range.

Differences in technique may partly account for the fact that the results of our differential thermal analysis seem

to conflict with the findings of other workers<sup>1-4</sup>, but a more important factor almost certainly is the nature of the tissues used in the investigation. The annulus fibrosus and to a greater extent the nucleus pulposus contain much greater quantities of glycosaminoglycans and non-collagenous proteins (of several different types)<sup>10</sup> than the collagenous tissues investigated previously. In both areas of the disk the total amount of glycosaminoglycans, on a dry weight basis, decreases with age and also the chondroitin sulphates: keratan sulphate ratio<sup>7</sup>. On the other hand, the amounts of non-collagenous proteins increase greatly with age (ref. 9 and succeeding communication).

Conclusive evidence of the stabilizing role of the polysaccharides or other carbohydrates is difficult to obtain<sup>1</sup>, and the possible influence of non-collagenous proteins on collagen has received very little attention. There seems to be, however, little doubt that such compounds can have a significant effect on the mechanical properties of collagen<sup>11,12</sup>. It should be emphasized that pure collagen has not been isolated from the disk and that much larger quantities of sugars and non-collagenous proteins seem to be firmly bound to the fibres<sup>7,13</sup> than in other tissues, with the possible exception of cartilage. These firmly bound components probably have a greater effect on hydrothermal stability than the remainder of the ground substance and their complexes with collagen may be particularly important in the young nucleus pulposus, the collagen of which is very poorly crystalline. It is suggested that the collagen present in older specimens of nucleus pulposus has a lower hydrothermal stability than such complexes, even though it is more crystalline and, presumably, has a greater degree of crosslinking. This interpretation is supported by the relative values of  $T_1$  obtained for the annulus fibrosus and nucleus pulposus. The greater crystallinity of the annulus fibrosus at all ages is not reflected in the results until after the age of about 10 (compare Figs. 2 and 3), when the hydrothermal stability becomes increasingly dependent on the integral structure of the collagen molecules, rather than on the presence of other compounds. More information is required about the effect of ageing on the association of collagen and other tissue components before this hypothesis can be tested further.

Another factor which may be relevant is that different mechanical treatments can raise or lower the shrinkage temperature of tendon collagen<sup>14</sup>. The mechanical forces on the disk *in vivo* are quite different from those to which other tissues are subjected and could be partly responsible for the unusual effects of ageing which we have observed.

## Variations in the Protein Components of Human Intervertebral Disk with Age

CHANGES in the glycosaminoglycans of the human intervertebral disk with ageing have been reported by a number of authors (see Antonopoulos<sup>1</sup> for recent work). On the other hand, there have been few investigations of the protein components, although they make up the larger part of the tissue. The collagen content has been determined in the central portion of the disk<sup>2</sup> (the nucleus pulposus) at different ages. Similar analyses have been made on the nucleus pulposus and on the surrounding annulus fibrosus<sup>3</sup>. X-ray diffraction<sup>4</sup> has indicated that at least one of the non-collagenous proteins present in the nucleus pulposus increases with age, but except for a brief reference by Hallén<sup>5</sup>, chemical data on these components are lacking. In the present investigation the effects of ageing on the non-collagenous protein nitrogen and on the tyrosine, most of which also derives from the non-collagenous proteins<sup>6</sup>, were investigated in addition to the collagen.

Specimens of apparently normal lumbar disks were obtained at autopsy and the nucleus pulposus and annulus fibrosus dissected out, discarding the intermediate zone. The material was homogenized and simultaneously dehydrated in ethanol, and allowed to equilibrate with the atmosphere before analysis. Tyrosine was determined using the 1-nitroso-2-naphthol reagent<sup>7</sup>, after dissolving the sample by a short treatment with 50 per cent hydrochloric acid at 100° C, as previously described<sup>8</sup>. Hydrolysis was carried out for 24 h before the determination of hydroxyproline by the Woessner method<sup>9</sup>.

The results for four different age groups are shown in Table 1. Differences between mean values, discussed below, were considered to be significant only when statistical analysis indicated that this was true at the 5 per cent level ( $P = 0.05$ ) at least. The percentage of hydroxyproline, and thus the collagen content, did not show a significant trend in the first three groups of the nucleus pulposus, but a lower result was obtained for group 4. In the annulus fibrosus hydroxyproline decreased from group 1 to 3 and then remained constant. These results contrasted sharply with those obtained for total nitrogen (Kjeldahl method). In the nucleus pulposus group 3 gave

a much larger value than group 1, whereas these groups of the annulus fibrosus showed almost identical values. It therefore seemed certain that appreciable changes had occurred in the amounts of the other proteins and the results calculated for non-collagenous protein nitrogen indicated a very significant increase from group 1 to 3 in both regions of the tissue.

A decrease in the absolute amount of collagen is feasible, for example, by an enzyme digestion similar to that which has been demonstrated in cartilage<sup>10</sup>. Collagen, however, usually shows very little metabolic turnover and it seems probable that the decrease in the percentage value of this protein in the annulus fibrosus was a dilution effect, caused by the large increase in the amount of non-collagenous proteins. In the first three age groups of the nucleus pulposus this effect would be at least partly nullified by the decrease in the glycosaminoglycan content, which is appreciable up to the age of about 60 yr<sup>1</sup>. A small increase in the absolute amount of collagen may actually have occurred. It should be pointed out that the dry weight of the tissue increases with age<sup>1</sup>, but the proportionate increase in analytical values, when expressed on a volume basis, will be the same for each component.

The results for tyrosine generally confirmed the age trend shown by the non-collagenous protein nitrogen, but the relative values obtained in the two determinations require some comment. Assuming a nitrogen content of about 16 per cent for the non-collagenous proteins, which have not yet been isolated in a pure form from the disk, the amounts of these components varied from approximately 20 per cent to 45 per cent in the nucleus pulposus and from 5 per cent to 25 per cent in the annulus fibrosus. Even when allowance was made on the basis of a tyrosine content of 1 per cent for human collagen<sup>11</sup>, although the true value is probably smaller, the other proteins of the nucleus pulposus seemed to contain 6 per cent to 9 per cent of this amino-acid. These values tended to increase from group 1 to 3, but the opposite effect was found in the annulus fibrosus, indicating that different non-collagenous proteins are deposited in the two regions of the disk. The tyrosine-rich protein that accumulates in the nucleus pulposus may account for the increased  $\beta$  protein type of X-ray diffraction reflexion on ageing<sup>4</sup>. A similar reflexion has not been established for the annulus fibrosus.

Ageing appears to have a much smaller effect on the non-collagenous proteins of human cartilage<sup>12</sup>, and analyses of similar proteins present in bovine cartilage<sup>13</sup> have given smaller values for tyrosine than those discussed above. The indirect method of calculation used here can only be approximate, but the results for the total dry tissues and for aqueous extracts<sup>8</sup> certainly suggest that unusually large amounts of tyrosine are present in the disk. The small amount of positive interference reported recently<sup>14</sup> for certain aromatic compounds in the 1-nitroso-2-naphthol

Table 1. COMPOSITION OF LUMBAR DISKS AT DIFFERENT AGES

	Nucleus pulposus			
	1 3-10 yr	2 20-50 yr	3 54-62 yr	4 65-80 yr
% Total nitrogen	9.6 ± 0.60 (5)	9.0 ± 1.2 (5)	11.1 ± 0.57 (6)	11.0 ± 0.45 (5)
% Hydroxyproline	3.2 ± 0.39 (5)	3.1 ± 0.60 (4)	3.9 ± 0.74 (7)	2.8 ± 0.55 (4)
% Tyrosine	1.5 ± 0.19 (5)	2.2 ± 0.54 (5)	2.3 ± 0.29 (7)	3.8 ± 0.25 (7)
% N.O. protein nitrogen*	3.2 ± 0.30 (5)	4.3 ± 0.88 (4)	5.6 ± 0.85 (6)	7.4 ± 0.82 (3)
	Annulus fibrosus			
	1	2	3	4
% Total nitrogen	13.1 ± 0.81 (5)	11.4 ± 0.82 (5)	13.0 ± 0.50 (7)	12.7 ± 0.72 (7)
% Hydroxyproline	9.1 ± 0.67 (5)	7.5 ± 1.2 (5)	6.4 ± 0.84 (7)	6.3 ± 0.79 (8)
% Tyrosine	1.8 ± 0.14 (5)	1.7 ± 0.22 (4)	2.3 ± 0.20 (7)	2.6 ± 0.27 (7)
% N.O. protein nitrogen*	0.9 ± 0.51 (5)	1.3 ± 1.1 (5)	4.2 ± 0.56 (7)	4.2 ± 0.78 (7)

Results are expressed as percentages of oven-dry tissues. The mean values for each age group are shown ± one standard deviation. Numbers of specimens are in parentheses. Hexosamine nitrogen was calculated from Hallén's data<sup>5</sup>.

\* Non-collagenous protein nitrogen = total nitrogen - (collagen nitrogen + hexosamine nitrogen).

Collagen nitrogen = hydroxyproline ×  $\frac{18.0}{13.7}$

colorimetric technique, was not likely to be significant in the present context, but further investigations on the specificity of this procedure are needed.

On the other hand, losses of tyrosine can occur during acid hydrolysis<sup>14</sup>, perhaps particularly when appreciable quantities of polysaccharides are present<sup>8,15,16</sup>. This difficulty was avoided in the present work, because complete acid hydrolysis is not necessary when the 1-nitroso-2-naphthol reagent is employed<sup>8,7,18</sup>.

The results obtained for hydroxyproline by the Woessner method were contrary to those reported by Mitchell *et al.*<sup>3</sup> and Rodighiero *et al.*<sup>3</sup>, who observed an increase with age. These workers employed the Neuman and Logan method<sup>17</sup>, which is liable to give large results in the presence of tyrosine<sup>8</sup> or other tissue components<sup>18</sup>, and the errors probably increased with the age of the disk. It would be surprising if this factor alone was responsible for the complete lack of agreement with our findings, but it is worth noting that some of the hydroxyproline values given by Rodighiero *et al.*<sup>3</sup> for the annulus fibrosus were close to that expected for pure mammalian collagen, although their results for total nitrogen and hexosamine indicated that quite large amounts of non-collagenous substances were present. The differences between our results and those of Hallén<sup>8</sup> for the nucleus pulposus are less disturbing, especially when the difficulty in distinguishing the two regions of the tissue in the older specimens is considered.

There can be little doubt that the large changes in the ratio of non-collagenous proteins to collagen which we have observed will affect the mechanical properties of the nucleus pulposus and annulus fibrosus, as suggested for other tissues<sup>19</sup>. The variations in the amount and composition of the glycosaminoglycan fraction have similar implications<sup>20</sup> and the presence of protein-polysaccharide complexes must also be considered. The nitrogen content of such complexes increases with the age of the disk<sup>21</sup>, which is interesting in relation to our results for non-collagenous protein nitrogen, but a more comprehensive investigation of these macromolecules in relation to age is now required.

## Interlocked Stresses in Cartilage

SPECIFICALLY aligned tensile stresses have been demonstrated in human costal<sup>1</sup> and nasal septal cartilage<sup>2</sup>. The outer layers of the tissue are maintained in tension so that the intact cartilage has a balanced system of forces the resultant of which is zero<sup>3</sup>. The nasal septal cartilage exists as a plate dividing the nose into two cavities in front and may become distorted in shape *in vivo* or *in vitro* if this balance of forces is altered. Breaching the surface layers on one side will partially release the interlocked stresses of the opposite intact side and because the cartilage is not rigid it will curl towards the intact side. The degree of deformation by curling has been shown to depend on the thickness of the cartilage and the cellular alignment which actually determines the alignment of the tensile stresses within the tissue<sup>4</sup>.

Relevant to the organization of forces within cartilage is the capacity of collagen and protein-polysaccharides in combination to bind large quantities of water. Sufficient external pressure will squeeze out fluid from cartilage and in the recovery of this or similar fluid the cartilage exhibits "swelling pressure". The importance of this and the rapid movement of water within cartilage under external stress have been shown in articular cartilage<sup>5</sup>. The appearance of the collagen network in nasal septal cartilage shows it to be under stress from an expansile force<sup>6</sup>. All available evidence suggests that the tensile stresses referred to must be set up against the "swelling pressure" of the cartilage. The present investigation is concerned with the role of the major components of cartilage in the organization of the tensile stresses. An experimental technique was evolved which demonstrated against a control situation the effect of selective destruction of each of the major components on the capacity of the cartilage to curl after artificial release of the tensile stresses of one surface.

Any two adjacent strips cut from the same septal cartilage will deform about equally if the same surface of each strip is interrupted by parallel cuts 1 mm apart. These parallel cuts are made about half way through the cartilage so as to breach the continuity of one surface only. If a whole septal cartilage is cut into strips of equal width, the alternate strips can be taken as a control group. If the interlocked stresses are abolished or reduced in the experimental strips, those strips show absent or reduced deformation after incision as compared with their controls. This technique was used in the investigation to study the role of the principal components of cartilage, cells, protein-polysaccharides and collagen in the system of interlocked stresses.

Nasal septal cartilage obtained from neonatal and infant cadavers within 24 h of death was cut into strips of equal width. Alternate strips were taken for the experimental and control groups. The cartilage was tested for deformation by curling while kept moist in air with Krebs-Ringer phosphate. Dry weights of the strips were obtained at the conclusion of the experiment.

The cells were killed or their metabolism inhibited by two methods. In the first, thirty-five matched pairs of cartilage strips were taken and the experimental group was frozen with liquid nitrogen and thawed three times. In the second, thirty matched pairs were taken and the experimental group incubated in 1 per cent sodium cyanide in Krebs-Ringer phosphate for 12 h. In both experiments, the deformation was equal in treated and control groups after the release of stress at room tem-

perature. The results indicate that the interlocked stresses were not maintained by cellular activity but were rather a property of the tissue already laid down.

The protein core of the protein-polysaccharide complex was hydrolysed in one experimental group by incubating the strips with inactivated mercuri-papain. Control strips were incubated in medium without enzyme for corresponding periods of time. Thirty-one matched pairs of cartilage strips were used for these experiments. Incubation with 5  $\mu$ g/ml. papain for 1 h or with 0.5 mg/ml. hyaluronidase for 48 h completely abolished interlocked stresses. Lower concentrations of enzymes partially abolished stresses. Thirty-one matched pairs of cartilage strips were used in these experiments. Other physical properties of the cartilage and its elasticity and shape were virtually unaffected by either enzyme at these concentrations. Strips treated with either enzyme lost a major part of their chondroitin sulphate (sulphated glycosaminoglycans) to the medium, but lost practically none of their collagen (hydroxyproline). The average loss of weight was 15 per cent.

The collagen fibrillar network was degraded by incubating the experimental groups with 0.25 mg/ml. collagenase for variable periods (2–48 h). Eighteen matched pairs of cartilage strips were used in these experiments. The earliest observed effect of collagenase was to make it more plastic. Interlocked stresses were not, however, abolished until the elasticity had completely disappeared and the cartilage had become an amorphous mucoid mass. By this time much of the cartilage had gone into solution (68 per cent weight loss) and, with continued incubation, dissolved completely. Analysis of residual cartilage at several times during enzyme incubation indicated that as the collagen was degraded the whole cartilage went into solution—the hydroxyproline and protein polysaccharide concentrations in the cartilage remaining fairly constant.

When heated to 60° C, collagen fibres contract sharply. Incisions were made on one surface of the experimental and control groups of twelve matched cartilage strips producing deformation. The experimental group was incubated at 60° C for 10 min and the deformation was

Fig. 1. Illustration of the experimental technique used in this investigation. Right matched pairs of nasal septal cartilage strips are shown, the control and experimental groups being marked. • the experimental group on the right was incubated with 5  $\mu$ g/ml. of papain for 1 h. The control group on the left was incubated in medium without enzyme.

Fig. 2. Photograph taken 10 min after multiple incisions on one surface in both groups as described in the text. The control group shows the expected curl; the experimental group shows no curl because the interlocked stresses have been abolished.

no different from that of control strips. This suggested that the shrinkage of collagen did not affect interlocked stresses, indicating that specific arrangement of collagen did not determine stress alignment.

These results suggest that the protein-polysaccharides of cartilage are intimately involved in establishing differentially aligned interlocked stresses. Collagen appears to play no part in the orientation, but rather seems to act as a skeleton forming point of anchorage for the protein-polysaccharides. Other evidence suggests that these tensile stresses are set up against the swelling pressure of the cartilage.

## PHYSIOLOGY

### A System Linking the Third Ventricle with the Pars Tuberalis of the Rhesus Monkey

IN the course of studies of the hypothalamus of the rhesus monkey, we have investigated a restricted area of specialized ependymal cells. This area lies anterolaterally in the tuber cinereum (see Fig. 1), and is distinguished by the long processes of the ependymal cells which extend to the region of the pars tuberalis; neighbouring

ependymal cells are cuboid, without processes. The elongate ependymal cells stain deeply with the Gomori chrome-alum-haematoxylin technique and may be followed with ease using the optical microscope. They are not evident after silver impregnation techniques (Bodian's silver protargol method or Bielschowsky's technique), nor are they detectable after performic acid-alcian blue staining; they can, however, be demonstrated by cresol fuchsin and aldehyde fuchsin and the periodic acid-Schiff (PAS) method.

Under the electron microscope the ependymal cells are seen to have, in addition to a few cilia, a great number of fine microvilli. The prolongations of these cells branch and appear to terminate at the junction of the pars tuberalis and the median eminence either on the walls of the hypothalamo-hypophyseal blood vascular system or in such a way as to make direct contacts with cells of the pars tuberalis. The fine branches of the ependymal processes are densely packed with membrane-bound electron-dense granules measuring about 600 Å in diameter; the terminal regions of these branches contain in addition electron-lucent vesicles about 250 Å in diameter. The contacts between the terminals and cells of the pars tuberalis are synaptoid, inasmuch as they contain clusters of electron-lucent vesicles, but no clear signs of additional electron density along the region of contact between the terminals and the pars tuberalis cells could be seen.

Some observations made on animals treated with 17- $\beta$  oestradiol indicated a possible role of the specialized periventricular ependymal system described here in the regulation of pituitary function, and some preliminary experiments were therefore undertaken to investigate this possibility.

Twelve hours after an intramuscular injection of tritium-labelled 17- $\beta$  oestradiol, samples of the cerebrospinal fluid and blood plasma were tested for radioactivity in a scintillation counter. Radioactivity was found in both samples, that of the cerebrospinal fluid being approximately one-eighth of that found in the plasma. Twelve hours after a similar injection of labelled oestrogen to an ovariectomized female monkey, its hypothalamus was sectioned by freezing microtomy and examined by autoradiography. A strong concentration of silver grains was found in the area of the specialized ependyma described, but not elsewhere.

Under the electron microscope, the specialized ependymal cells of animals injected with oestrogen were seen to contain irregular globular electron-dense masses, but these were not found in control animals.

Fig. 1. Relationship of a specialized ependymal region to the hypothalamus and pituitary of a rhesus monkey. Sagittal, transverse and horizontal sections are shown above and at the right and left respectively. V, Ventricle; Z, zone of specialized ependymal cells.

The results of these preliminary experiments therefore suggest that the cerebrospinal fluid acts as a vehicle for oestrogen or its metabolites and that these may be selectively absorbed by certain specialized ependymal elements. It is interesting to note this relationship between circulating oestrogen and ependyma of the infundibular recess, in view of the known physiological relationship between this area of the hypothalamus and the anterior pituitary.

A possible role of modified ependymal elements in the regulation of anterior pituitary function has already been suggested<sup>1</sup> and a possible role of the cerebrospinal fluid in neuro-endocrine regulation has been postulated<sup>2,3</sup>. The studies described here support this postulate by demonstrating a link between the third ventricle and the pituitary in the rhesus monkey.

### Observations on the Pars Intermedia of *Xenopus laevis*

THERE have been conflicting reports of the innervation of the pars intermedia of the amphibian pituitary. Dawson<sup>1</sup> found material coloured by "neurosecretory" stains in the pars intermedia of *Rana pipiens*, but Iturriza<sup>2</sup> could find no neurosecretory fibres with typical elementary neurosecretory vesicles at the level of ultrastructure in the pars intermedia of *Bufo arenarum*. Instead, fibres containing smaller vesicles were noted and subsequent investigations have indicated that these fibres contain monoamines, and may inhibit secretion of melanocyte stimulating hormone (MSH) from the pars intermedia<sup>3,4</sup>.

Electron microscope studies of the pituitary of *Xenopus laevis* support the view that in amphibians the pars intermedia is penetrated by fibres of the monoamine-containing type. These fibres stained with silver stains but not with chrome-alum-haematoxylin or alcian blue techniques. Under the electron microscope they were seen to contain two kinds of inclusion: (a) vesicles about 800 Å in diameter, irregular in form, each containing an electron-dense granule about 550 Å in diameter separated from the vesicular membrane by a clear electron lucent space; (b) smaller electron lucent inclusions about 400 Å in diameter. In many respects these fibres therefore resemble the type B fibres described by Knowles in the elasmobranch pituitary<sup>5</sup>; it seems probable that this form of innervation of the adenohypophysis is a consistent feature of the vertebrate pituitary<sup>6</sup> and should be termed neurosecretory<sup>7</sup>.

No direct synaptoid contacts between these type B fibres and pars intermedia cells, as have been noted in hippocampus<sup>8</sup>, were seen, but in many instances the fibres were enveloped by pars intermedia cells and it seems likely that functional contacts are made.

A diligent search did not reveal any deep penetration of the pars intermedia by type A fibres though some were seen to traverse the boundary between the pars nervosa and pars intermedia and others appeared to discharge into the vascular spaces which lie between the pars nervosa and pars intermedia. A dual control of pars intermedia function by type A and type B fibres, as in the dogfish pituitary<sup>9</sup>, cannot be excluded.

Experimental data lend support to the view that MSH synthesis and MSH release in *Xenopus* may be separately controlled. Under dim illumination and in darkness the melanophores assumed an intermediate condition (M.I. 2.5-3.5); in bright illumination with the animal on a white background they concentrated maximally (M.I. 1-2); and on an illuminated black background they were maximally dispersed (M.I. 4-5). A study of the ultrastructure of the pars intermedia cells did not reveal corresponding changes. The cells of animals adapted to a black background contained an extensive endoplasmic reticulum but few secretory vesicles, indicating active hormone synthesis and release. On an illuminated white background endoplasmic reticulum formation was also prominent though less abundant, and secretory vesicles were numerous: this indicates synthesis but little or no release, a finding supported by bioassay<sup>9</sup>. Organized endoplasmic reticulum was almost absent from animals adapted to dim light or darkness. The changes in ultrastructure indicate that illumination promotes MSH synthesis but that release only takes place when the animal is on a black background.

These observations, when compared with those reported by other workers, argue in favour of a dual control of pars intermedia function in amphibians in which hormone synthesis and release are independently regulated. The electron microscope findings indicate that two kinds of neurosecretory fibre may be concerned.

### Reflex Withdrawal of the Eyecup in the Crab *Carcinus*

In the crab *Carcinus*, mechanical stimulation of an anterior area of the carapace supplied by the tegumentary nerve results in a rapid withdrawal of the eyecup on that side<sup>1</sup>. Sensory pathways in any of the other ipsilateral brain nerves can also elicit the downward and slightly backward reflex movement of the eyecup. The motor axons mediating the response are known to be in the optic tract<sup>2</sup>, but their peripheral connexions are unknown. The action of the eyecup muscles in the reflex has been studied here in the wider context of a survey of several eyecup movements<sup>3</sup>.

Fig. 1. Diagram of a right eye joint dissected from the lateral side to show the muscles involved in the withdrawal reflex. The flexible joint enables movement of the eyecup, to some extent, in all three planes. The nine eyecup muscles attach to internal projections of the eyestalk while muscle 18 rotates the eyestalk relative to a sclerite on the main body skeleton. The numbering of the muscles follows that of Cochran<sup>4</sup>.

Fig. 2. Responses recorded from the optic tract (middle traces) and from muscles 19a and 18 (upper traces) to a single shock applied to the tegumentary nerve (lower traces). Records are from different preparations. Scale: 20 mV, 40 msec.

Fig. 3. Recordings from pairs of muscles in different preparations. A, The junction potentials of 19a and 20a are in phase but those of 19a and 18 are not (B). 18 is, however, in phase with 21 (C), with 20b (D) and with 22 (E). This indicates the presence of two axons, one supplying 19a and 20a, the other 18, 20b, 21 and 22. Scale: 20 mV, 100 msec.

The normal pattern of nerve impulses which cause the eyecup withdrawal can be recorded from the optic tract when the eyecup is clamped, withdrawn or even absent altogether, and numerous experiments show that proprioception is of no importance. For convenience, therefore, the eyecup of a limbless crab was cemented into its socket and conventional intracellular electrodes recorded the muscle potentials through a small hole in the eyecup exoskeleton. The reflex was elicited by applying shocks of 1 msec duration to the tegumentary nerve. Motor impulses in the optic tract were recorded with the bared tip of a stainless steel insulated wire electrode.

During a withdrawal a train of efferent impulses of two different amplitudes can be recorded in the optic tract and this pattern cannot be broken down, even in a fatigued preparation, to more than two axons. The larger spike is correlated with junction potentials recorded simultaneously in eyecup muscle 19a, while the smaller is correlated with junction potentials in eyestalk muscle 18 (Figs. 1 and 2). These axons also branch to other muscles and junction potentials recorded in muscle 19a are in phase with those in a few fibres on the dorsal surface of muscle 20a (Fig. 3A). Similarly, junction potentials recorded in muscle 21 on the medial side of the eyecup, muscle 20b, a small vertically placed muscle, and muscle 22 are in phase with those recorded in muscle 18 (Fig. 3C-E). The junction potentials of muscles 19a and 18 are never in phase (Fig. 3B). Despite many penetrations of other eyecup muscles, phasic activity associated with eyecup withdrawal has not been recorded, but until it is certain that all the fibres have been penetrated these muscles cannot be completely excluded. Thus the axon with the large spike innervates muscles 19a and 20a, while the axon with the smaller spike innervates muscles 18, 20b, 21 and 22. Although the two muscle groups show the

same latency, the form of their response differs. The junction potentials in 19a and 20a rapidly facilitate and summate and graded active responses occur which sometimes overshoot zero. The responses in the second group are at a lower frequency and without active membrane events.

During optokinetic movements of the eyecup only muscle 19a is inactive. Fibres in the other muscles tend to fall into two classes: phasic ones which are active only during an eyecup movement and tonic ones which are also responsible for maintaining any eyecup position. This difference has a structural correlate in that phasic fibres have sarcomere lengths of 3–4  $\mu$ m, while those of tonic fibres are 10–12  $\mu$ m (ref. 5). Muscle 19a, however, is histologically uniform in that the fibres all have sarcomere lengths of 3–4  $\mu$ m. These fibres also showed similar activity during a withdrawal, differing only in density of innervation by a slow axon from the oculomotor nerve responsible for holding the eyecup in its socket, once withdrawn. In muscles 18, 20a, 21 and 22 only those fibres which respond phasically in optokinetic movements are innervated by the withdrawal axons, but in 20b some tonic fibres are also innervated.

During a withdrawal the tonic activity, which normally locates the eyecup in space, is modified, but not inhibited peripherally. Only the tonic activity in muscle 23a, on the dorsal surface of the eyecup, is inhibited centrally. The remaining tonic activity is presumably overridden mechanically by the strong phasic action of the withdrawal muscles.

When a statocyst is removed and other sensory input is kept at a constant low level, withdrawal of the ipsilateral eyecup occurs "spontaneously" about every 13 sec. This indicates the presence of a pacemaker in the brain which is usually counteracted by normal sensory input<sup>6</sup>. Up to 500 msec before such a "spontaneous" withdrawal the tonic activity in all the eyecup muscles is centrally inhibited (Fig. 4) and there is a slight slowing of the tonic activity in the contralateral eyecup (Fig. 4B). After this inhibitory period, slowly facilitating and summing junction potentials can be recorded in muscles 18, 20b, 21 and 22, that is the group supplied by the axon with the smaller spike recorded in the optic tract. These cause a depolarization plateau which may last for up to 500 msec, during which a high frequency burst of junction potentials can be recorded in muscles 19a and 20a, that is that group supplied by the axon with the larger spike recorded in the optic tract (Fig. 4A). These junction potentials facilitate and summate rapidly and active membrane responses occur. Although the firing sequence of the two axons differs from that in a reflex withdrawal, the overall movement of the eyecup as seen in an unclamped eyecup is similar.

Of the six muscles involved in the withdrawal reflex, all but 19a are active in optokinetic movements. For example, when muscle 21 is active with muscles 18, 19a, 20a, 20b and 22, a withdrawal movement downwards and

away from the midline occurs. During optokinetic movements, however, the same fibres in muscle 21 together with a specific pattern of activity in the other muscles are most active in a horizontal movement toward the midline. It is thus possible for one muscle, in conjunction with different patterns of activity in other muscles, to be involved in opposite movements. Interpretation of eyecup muscle activity therefore becomes intelligible only if a group of muscles, rather than the individual muscles themselves, are regarded as functional units.

### Variation in Physiological Properties of Crustacean Motor Synapses

THE properties of individual synapses of the motor axon which innervates the opener (dactylopodite abductor) muscle in the crayfish walking leg have been investigated by Dudel and Kuffler<sup>1</sup>, who placed an external micro-electrode close to the synaptic region to record the flow of current through the post-synaptic muscle fibre membrane during the action of the neuromuscular transmitter<sup>2</sup>. With low frequencies of stimulation of the motor axon individual synapses showed frequent failures of transmission, and the synaptic currents generated by successful transmission were small, often equal in size to a single externally recorded spontaneous miniature potential. The latter event was found to equal one quantal unit of transmitter action. At higher frequencies of stimulation, the probability of failure of transmission decreased, and the synaptic currents attained a larger average size, indicating that the output of transmitter substance from the presynaptic terminals had increased. The post-synaptic potentials recorded internally from the muscle fibres were correspondingly larger at the higher frequencies of stimulation. These observations indicate that facilitation at the crayfish neuromuscular junction is the result of some process which gives rise to a higher probability of release of transmitter substance at the higher frequencies of stimulation or during the course of a train of closely spaced stimuli.

Not all post-synaptic potentials set up in crustacean muscle fibres by a single motor axon show properties of facilitation. Some of the fibres in a muscle may show non-facilitating or poorly facilitating potentials, whereas others may show the more common facilitating potentials<sup>3</sup>. In the opener muscle of the crab *Pachygrapsus crassipes* Randall, facilitating and non-facilitating potentials have been observed in adjacent muscle fibres (Fig. 1). The question arises whether synapses of crustacean motor axons are variable in their behaviour, thus generating different types of post-synaptic potentials.

The properties of the synapses of the open-stretcher motor axon of *Pachygrapsus* were investigated by means of the technique of focal recording with an external microelectrode and it was found that some of the synapses behaved as described

Fig. 4. A, Recordings from muscle 19a (upper) and 20b (lower) during a "spontaneous" withdrawal. Note the preceding inhibition of tonic activity and that phasic activity in 20b precedes that in 19a. B, The effect on the contralateral tonic activity compared with that in the ipsilateral eyecup (O), during a "spontaneous" withdrawal. Scale: 20 mV, 500 msec (A), 500 msec (B and C).

by Dudel and Kuffler<sup>1</sup>. Failure of transmission was common at low frequencies of stimulation, and synaptic currents were small, usually only one or two quantal units in magnitude (Fig. 2A and B). The number of transmission failures decreased at higher frequencies of stimulation, and the average amplitude of the synaptic currents increased. In other endings, however, especially those on muscle fibres showing non-facilitating post-synaptic potentials, there were no failures of transmission at low frequencies of stimulation (1/sec or 0.5/sec). Synaptic currents were several times the size of the quantal unit (Fig. 2C and D). Often these currents varied little from one stimulus to the next (Fig. 2D). As the frequency of stimulation was increased, the currents showed no marked increase in amplitude. Apparently the powers of facilitation were rather limited in such endings.

It was often possible to record rather large nerve terminal potentials at the non-facilitating synapses (Fig. 2D). This suggests that the synapses are located on large-diameter axon branches, which may be capable of supporting a propagated action potential. The nerve terminal potentials recorded at the facilitating synapses were generally smaller. Possibly these synapses are located mostly on fine axon terminals, which may not conduct a propagated action potential, but rather a decremental response<sup>4</sup>.

Fig. 1 Facilitating (A and B) and poorly facilitating (C and D) post-synaptic potentials from two fibres in the opener muscle of *Paedopygus*. Calibration: voltage, 10 mV, time, 1 sec.

Fig. 2 Synaptic currents (top records) set up by 1/sec stimulation of the opener-stretcher motor axon of *Paedopygus*. Lower traces show the internally recorded post-synaptic potentials of the muscle fibres. Records were from a facilitating synapse (A and B) and from two poorly facilitating synapses (C and D). In the former, transmission failures were frequent (A) and currents small; A and B show currents of one and two quantal units, respectively. In C and D, currents were several times the quantal unit (the size of which is comparable with the spontaneous potential in C). A large nerve terminal potential precedes the synaptic current in D. Calibration: voltage 400  $\mu$ V (top traces) and 20 mV (bottom traces), time, 4 msec.

The above observations suggest that there are different types of synapse associated with a single motor axon, but that the ultimate basis for the differences has yet to be determined.

The ratio of facilitating to non-facilitating synapses supplied to a muscle fibre by a particular axon probably determines in large measure the properties of the post-synaptic potentials evoked by that axon. Different motor axons (for example, the "fast" and "slow" axons of certain leg muscles) may differ in the relative numbers of the various types of synapse they possess.

### Secretion of a Chromaffin Granule Protein, Chromogranin, from the Adrenal Gland after Splanchnic Stimulation

Banks and Helle<sup>1</sup> have reported that stimulation of the isolated bovine adrenal gland, during retrograde perfusion, releases not only catecholamines but also a soluble protein present in the chromaffin granules; this finding has since been confirmed<sup>2,3</sup>. We propose the term "chromogranin(s)" as suitable for the soluble protein fractions of the chromaffin granules of the adrenal medulla.

In order to determine whether the secretion of chromogranin from the adrenal medulla occurs in the living animal, we have looked at the adrenal glands of calves. We collected adrenal venous blood from a calf (aged 293 days) under pentobarbitone anaesthesia during and between periods of stimulation of the splanchnic nerve. The experimental conditions were as described by Comline and Silver<sup>4</sup> except that adrenal effluent blood was collected from a catheter inserted through the adrenal vein into the venous sinus of the gland. The main component of the chromogranins was purified by the method of Smith and Winkler<sup>5</sup> and a rabbit antiserum was prepared against the purified protein. This chromogranin was assayed by a complement fixation method that was accurate within the limits of 0.5–2.0 times the observed value.

The catecholamine and chromogranin contents of samples of adrenal venous plasma collected during, and after, three periods of nerve stimulation are given in Fig. 1. The secretion of the protein accompanied and continued after that of the catecholamines. The ratios of catecholamines ( $\mu$ moles) to chromogranin (mg) in the venous plasma during each of the 5 min periods were 3.3, 11.3 and 4.2; these ratios are of the same order of magnitude as that found for isolated chromaffin granules (unpublished work of Schneider, Smith and Winkler) which was  $10.1 \pm 3.9$  ( $n=10$ ). The results of this experiment are supported by observations on two calves under chloralose anaesthesia, in which the adrenal venous plasma was tested with the rabbit antiserum to the purified main component of the chromogranins; the plasma from one calf was tested by the Ouchterlony immunodiffusion method, and that from the other calf was examined by complement fixation. In both experiments the plasma collected during periods of stimulation contained much more chromogranin than did the plasma collected during control periods.

We conclude from these observations that the secretion of a soluble protein from chromaffin granules accompanies that of the catecholamines on stimulation of the splanchnic nerve *in vivo*. This adds further significance to the *in vitro* investigations which have shown that the entire

### Inhibition of Gastric Acid Secretion by a Purified Bacterial Lipopolysaccharide

LIPOLYSAOCHARIDES from Gram negative bacteria produce many systemic toxic effects when injected into experimental animals and are thought to institute the processes referred to in humans as endotoxic shock<sup>1</sup>. They act by altering regional blood flow and leading to ischaemia in critical areas of the body, especially the mid-gut<sup>2</sup>.

A direct relationship between gastric mucosal blood flow and gastric acid secretion has been demonstrated<sup>3</sup>, and injections of a purified lipopolysaccharide into dogs have reduced total gastric blood flow<sup>4</sup>, apparently through a mediating substance. We have tried to link the two sets

of observations and to investigate the effect of a bacterial lipopolysaccharide on the secretion of gastric acid.

A purified lipopolysaccharide, prepared as described before<sup>5</sup> from the lysine-dependent mutant *Escherichia coli* ATCC 12408, was supplied by Dr K. W. Knox. The preparation was diluted before injection with sterile phosphate buffer (0.1 molar, pH 7.4) to give the concentrations shown in Table 1. Secretion of gastric acid in sixty-five Sprague-Dawley rats weighing 85–180 g was measured by pylorus ligation<sup>6</sup>. Groups of six rats were injected intravenously with increasing concentrations of lipopolysaccharide at the time of pylorus ligation; they then rested for 4 h after which gastric juice was aspirated and the acid content was measured. Mean acid secretion by each group of rats was determined and the dose-response curve shown in Fig. 1 was constructed.

The results (Table 1, Fig. 1) show that the purified *E. coli* lipopolysaccharide was a powerful inhibitor of rat gastric acid secretion. Acid secretion was almost abolished by all doses of lipopolysaccharide greater than 50 µg/kg while secretion was reduced to 50 per cent of control values by a dose of 1.25 µg/kg (about 0.15 µg/animal). In agreement with earlier experiments we found that larger doses were toxic, the LD<sub>50</sub> in this experiment being 2 mg/kg.

It is probable that the reduced total gastric blood flow after injection of lipopolysaccharide is associated with reduced gastric mucosal blood flow which is the cause of the reduced secretion of acid. It is interesting to note that this effect on total gastric blood flow seems to be mediated by a separate substance produced in the body,

Fig. 1. Mean acid secretion by groups of rats given *E. coli* lipopolysaccharide expressed as a percentage of control.

Table 1. MORTALITY AND ACID SECRETION IN GROUPS OF RATS GIVEN INTRAVENOUS INJECTIONS OF *E. coli* LIPOLYSAOCHARIDE

No.	Dose (µg/kg)	Volume of buffer (ml/kg)	Mortality (per cent)	Acid secretion (mean)	m.equiv./100 g/4 h (standard error)
6	0	5	0	339	±40
5	1	5	0	191	±84
6	5	5	0	24	±4
6	10	5	0	45	±22
6	50	5	0	3	±2
6	100	5	0	3	±2
6	200	5	17	0	±0
6	500	5	17	3	±1

6	2,000	5	50	0	±2
6	4,000	5	66	3	±3

probably in the intestine, because it cannot be produced by lipopolysaccharide injected directly into the gastric vessels<sup>4</sup>.

Gastric acid secretion is very sensitive to intravenous injections of lipopolysaccharide and this agent seems to be one of the most potent of all inhibitors of acid secretion yet described. Other endotoxins are at present being prepared from a variety of Gram negative bacteria and their effects on gastric acid secretion will be assessed.

### Transmission from Excitatory Nerves to the Smooth Muscle Cells of the Rat Seminal Vesicles

THIS communication reports some investigations of transmission from excitatory nerves to the smooth muscle cells of the seminal vesicle of the rat. The seminal vesicles were dissected from adult rats and the preparation inserted between ring electrodes and bathed in a Hukovic solution<sup>1</sup>. The method used to stimulate the intramural nerves and the technique involved in recording with microelectrodes from the smooth muscle cells were the same as previously described<sup>2</sup>.

Stimulation of the intramural nerves with single pulses lasting 1 msec gave rise, after a latent period of about 8 msec, to a transient depolarization, the excitatory

Fig. 1. Effect of stimulating the intramural excitatory nerves to the seminal vesicles with single pulses. *a*, Excitatory junction potential arising from stimulating with a pulse of sub-maximal strength. *b*, Junction potential arising from stimulation with a supra-maximal pulse, leading to the firing of two action potentials. (Note different time scale in *a* and *b*.)

Fig. 2. Effect of repetitively stimulating the intramural excitatory nerves to the seminal vesicles. *a*, Successive junction potentials after the first are much smaller in amplitude, stimulation frequency 2 c/s. *b*, First junction potential of a train fires an action potential, but succeeding junction potentials do not, stimulation frequency 1 c/s. *c*, High frequency of stimulation (20 c/s) only transiently depolarizes the muscle cells because of the decrease in amplitude of successive junction potentials. Note repetitive firing of action potentials during depolarization. The microelectrode became completely dislodged by muscle contraction before the membrane repolarized during stimulation.

junction potential, which decayed exponentially with a time constant of about 150 msec (Fig. 1*a*). It was possible to depolarize the smooth muscle cells by passing a current through them by means of an intracellular electrode. I found that the membrane time constant was only about 2–3 msec, which is much less than the time constant of the excitatory junction potential.

When the stimulation applied to the intramural nerves was increased, the amplitude of the excitatory junction potential increased in at least five steps. This suggests that each smooth muscle cell is affected by at least five axons. When the excitatory junction potential reached an amplitude of about 25 mV, an action potential was initiated with an overshoot of 15 mV and a maximum rate of increase of 12 V/sec (Fig. 1*b*). Successive excitatory junction potentials arising from repetitive stimulation of the intramural nerves at 1 c/s with pulses of supra-threshold strength decreased in size until a steady

amplitude was reached (Fig. 2a and b). At high frequencies of stimulation the membrane was only transiently depolarized (Fig. 2c). When the interval between the pulses was greater than 30 sec, however, it was no longer possible to detect decreases in the amplitude of the excitatory junction potential.

The very short latency of 8 msec indicates that the time between stimulus and the beginning of the release of transmitter from autonomic axons is less than this. The large latencies found for transmission from intramural nerves to the smooth muscle cells of the guinea-pig taenia coli<sup>2</sup> and the rabbit colon<sup>4</sup> should therefore be attributed to other factors in the transmission link. Although transmissions from the hypogastric nerves to the vas deferens<sup>4</sup> and from the pelvic nerves to the distal colon<sup>4</sup> are known to be enhanced by facilitation, no facilitation has been observed from intramural inhibiting nerves to the taenia coli<sup>2</sup>. The present investigation indicates that there may be a depression of transmission from some autonomic nerves to smooth muscle with successive stimuli.

### Isolated Double Perfusion of the Liver in the Study of the Reticulo-endothelial System

THERE is still disagreement about whether reticulo-endothelial function depends on a serum factor<sup>1-3</sup>. There is substantial evidence that in certain mammals, especially the rat, "reticulo-endothelial phagocytosis" requires the participation of a serum factor for certain colloids. In this species, blockade of the reticulo-endothelial system can be attributed to depletion of a serum factor, perhaps antibody or a complement component. By contrast, in the rabbit, reticulo-endothelial blockade can occur independent of serum factors<sup>4</sup>, and experimental agammaglobulinaemia in the chicken is not associated with any deficiency of reticulo-endothelial clearance *in vivo*<sup>5</sup>. Until now, however, no critical evidence has been presented about the exact nature of the serum factor operating in the rat system or the nature of the blockade in animals not requiring the serum factor.

We have tried to simplify the experimental system and isolate for study the factors involved. We chose organs primarily involved in reticulo-endothelial function and wanted to be able to manipulate the contributions of serum and colloid in a system more easily controlled than the *in vivo* systems generally used. We therefore used the double liver perfusion system shown in Fig. 1. This system is a modification of the system described by us in 1961, which was a simplification of the methods used by Miller<sup>6</sup>. It makes it possible to test protein synthesis and bile formation<sup>7,8</sup> in the perfused liver.

The single perfusion apparatus was modified so that a single isolated liver could have its entire perfusate changed without interrupting the circulation through the liver. This "double perfusion" apparatus is simply two single systems combined. The perfusate used was a mixture of total fresh blood taken from Sprague-Dawley rats and heparinized (500 u/ml.) with Tyrode solution (pH 7.6-7.4) in the ratio of 3:1.

20 mg of aureomycin and 800 mg of dextrose were also added. The total volume of perfusate was 100 ml. The liver was isolated from a Sprague-Dawley rat anaesthetized with 'Nembutal' (3 mg/100 g body weight).

After mid-line laparotomy, the bile duct was cannulated with a polyethylene catheter. Then the stomach was removed to reveal the liver and the portal vein cannulated with a cannula 1 mm in diameter. Another cannula was placed in the inferior vena cava at the level of the thorax. The liver was rapidly removed and connected to the apparatus; the period of anoxia was less than 3 min. The flow through the liver was kept constant at  $15 \pm 1$  ml./min.

To measure the speed of the clearance by the liver, we chose radioactive 'Auroclod' (Abbott) containing gold-198. The disappearance of the gold in the perfusate was followed by analysing the radioactivity of serial samples taken every 5 min. The activity of the samples was counted in a solid scintillation counter and reported as c.p.m. after correction for background.

Fig. 1. Double perfusion apparatus for the isolated liver. (1) Liver in plastic chamber. (2) Reservoir for perfusate. (3) 'Magnestar' providing homogeneous mixing of the perfusate. (4) Glass 'lung' in which perfusate is oxygenated. (5) Humidifier for oxygen. (6) Filter. (7) Pump. (8) Heater with thermostat maintaining temperature at 96° F. (9) Stopcocks. (10) Flowmeter. (11) Cabinet containing the system.

In our first series of experiments, we found that the clearance of gold in a liver perfusate decreased with time. Also, when a second or third dose of 'Auroclod' was added, the clearance was similar, although less rapid and less complete than that of the preceding identical dose of colloid. Our results show that this phenomenon is reversible in the isolated liver preparation. When 2.5 mg 'Auroclod' was added 3 min after the start of perfusion, half the gold was cleared from the perfusate 10 min later (Fig. 2). The same dose was again added at 40 min; 50 per cent clearance took 14 min. After the third dose, the time taken for 50 per cent clearance was 23 min. When we then changed the entire perfusate at 155 min, thus using rat blood fresh to the liver, and added another similar dose of 'Auroclod', the time required to clear 50 per cent of the circulating gold was again short, 8 min; after another dose only 14 min, and a final dose 21 min. It is clear from these experiments that diminution of the rate of clearance of gold may be increased simply by changing the perfusate for fresh, previously unperfused, rat blood. We interpret these observations as indicating that rat serum contains a factor which may be exhausted by the initial repeated perfusion of gold, and which is renewed by adding fresh rat blood to the perfusing system. We think that the decreasing rate of clearance observed initially is due to exhaustion of the serum factor and not to functional blockade of the reticulo-endothelial cells or to a shift in site of phagocytosis. In

Fig. 2. Demonstration by double-perfusion technique of the dependence of reticulo-endothelial blockade on blood. Ordinate, percentage of radioactivity present in the perfusate taking the 3 min sample as 100 per cent. At the top of the Figure, the arrows indicate addition of 'Aurocolloid', 2-5 mg. Abscissa, time in min.

our experiments, careful monitoring of the outflow of blood and the controlled circulation allowed us specifically to exclude outflow circulatory block as a basis for the decrease in function. Furthermore, varying the timing of the point of administration of the colloidal gold after the beginning of perfusion indicated clearly that the circulating factor was not being used non-specifically or metabolized by the liver.

Numerous repetitions of this type of experiment in this system have established that the method used is reproducible. Comparison of rabbit with rat livers, rat blood with rabbit blood or perfusates lacking serum factors, and the critical effects of dosage and continued presence of added colloid can be evaluated, as can the critical effects of specific antibody, complement or other serum factors. Indeed, this method should be valuable in obtaining critical analysis of reticulo-endothelial function in the absence of many factors difficult to control in the intact animal. In experiments similar to those described, but comparing non-serum containing perfusate and rat serum, it was found that serum factor is not required for phagocytosis, but that rat serum increases the rate of clearance of different circulating particles during perfusion of the isolated liver.

## Nystagmus induced by Unilateral Labyrinthectomy affected by Sleep-Wakefulness Cycle

It has been reported that post-rotatory nystagmus is replaced by slow ocular movements during behavioural sleep in children<sup>1</sup>. Sleeping infants are also said to show no nystagmus<sup>2</sup>. In cats a decrease in wakefulness as revealed by the electroencephalogram has been recently shown to be paralleled by a reduction of rotatory nystagmus<sup>3,4</sup>. We have investigated the modifications induced by the sleep-wakefulness cycle in "spontaneous" nystagmus after unilateral labyrinthectomy<sup>5</sup>.

The experiments were performed on cats. Screw type electrodes were implanted, under 'Nembutal' anaesthesia, in the skull for electroencephalogram recording and in the superior wall of the orbital cavity of each side, after the frontal sinuses had been opened, for recording ocular movements. Stainless steel electrodes were inserted into the posterior cervical muscles for electromyogram recording. During the same session the animal had one labyrinth destroyed through the bulla. On the day after the operation the cat was placed in a sound-proof room and records were made by an ink-writer electroencephalograph for several hours during the day.

Unilateral labyrinthectomy induced a regular horizontal nystagmus with the quick component toward the normal side. During wakefulness with desynchronized electroencephalogram and high cervical electromyogram the nystagmus was recorded on the electro-oculogram as regular high amplitude oscillations at a frequency of about 1/sec (Fig. 1A). These deflexions were not generally modified when the animal closed its eyes as long as it was awake. As the cat became more relaxed with lower cervical electromyogram and electroencephalogram synchronization the nystagmus seemed to be irregular, reduced in amplitude and it often disappeared synchronously with the cortical spindles (Fig. 1B). Nystagmic oscillations comparable with those found in wakefulness could be present during the interspindle hulls (Fig. 1B). When

Fig. 1. Cat one day after unilateral labyrinthectomy. Posterior cervical electromyogram (EMG), bifrontal electroencephalogram (EEG) and ocular movements, measured by electro-oculogram (EOG). Note the regularity of "spontaneous" nystagmus during wakefulness (A) and its modifications during synchronized (B and C) and desynchronized sleep (D). The nystagmus reappears at the moment of arousal (E) induced by a natural stimulus (at the arrow).

the electroencephalogram became highly and persistently synchronized, particularly in the phase immediately preceding a period of desynchronized sleep, the nystagmus disappeared and was replaced by low voltage irregular oscillations (Fig. 1C).

The appearance of a spontaneous episode of desynchronized sleep was characterized by deep changes in the electro-oculogram. Slow irregular ocular movements were present, at times interrupted by high voltage rapid eye movements typical of this phase of sleep\* (Fig. 1D). Sometimes ocular movements which resembled the nystagmic oscillations of wakefulness could be recorded independently of the rapid eye movements.

Any natural stimulation able to yield an electroencephalographic and behavioural arousal either from synchronized or desynchronized sleep invariably induced the reappearance of high voltage regular nystagmic movements (Fig. 1E).

The effects of the sleep-wakefulness cycle on nystagmus after unilateral labyrinthectomy could be observed only for 4-5 days because from then on the "spontaneous" nystagmus faded away confirming previous findings\*.

The results suggest that the mechanism of nystagmus which follows unilateral labyrinthectomy in cats may be actively inhibited by the nervous structures involved in the synchronization and desynchronization of the electroencephalogram during natural sleep.

### Multimodal Interneurons in Cockroach Cerebrum

By means of stainless steel microelectrodes, we have recorded multimodal interneurons in the protocerebrum of the cockroach, *Periplaneta americana*. At least two basic types of interneurons were recorded; one was excited by visual and a variety of mechanical stimuli, while the other was excited by visual stimuli and inhibited when abdominal movements occurred. Interneurons similar to one or the other of these two types have previously been reported in the optic lobe and protocerebrum of the migratory locust, where they also showed auditory responses<sup>1</sup>, in the optic nerve of decapod crustaceans<sup>2</sup>, and in moth protocerebrum<sup>3</sup>. In spite of these similarities, however, the cockroach units also showed certain distinct properties of their own.

Cockroaches were first anaesthetized with ether and then fixed in wax by pouring liquid paraffin of low melting point over them. The wax was then scraped away to expose the head, abdominal spiracles, and other body regions as necessary. Sufficient cuticle was removed to reveal the brain. The brain was desheathed before the electrodes were inserted. Electrodes were made from stainless steel insect pins etched with acid to a tip diameter of 1-2  $\mu$  and insulated to the tip with lacquer<sup>4</sup>. The light source was a standard low voltage microscope lamp, while tactile stimuli were delivered with a fine glass rod.

Most of the multimodal interneurons observed had a fairly slow somewhat irregular spontaneous discharge rate of 1-10/sec and were presumably large, because they

produced spikes nearly twice the amplitude of other units recorded. They responded with a brief burst of spikes when the light was turned off, to gentle touches on abdomen or pterothorax, and to gentle touches or brief displacements of cerci and tarsal segments. The duration of the bursts varied roughly from 0.1 to 1 sec, depending on the stimulus parameters. The first response of a series was usually the most marked; this was especially true when the light was turned off, where bursts following 30 sec or more in light contained more spikes and had shorter latency than those following briefer periods of light adaptation. Some units occasionally also responded when the light was turned on and when the ipsilateral antenna was displaced. These responses were, however, somewhat ambiguous. Only antennal responses depended on unilateral stimuli; all the others were elicited more or less equally effectively by stimuli applied either on the same or on the other side (Fig. 1).

The precise anatomical location of these units was not determined, but the approximate position was ascertained from surface contours and depth of electrode penetration. They occurred in the protocerebrum ventral and lateral to the mushroom bodies in a region of several large fibre tracts<sup>5</sup>. Insertion of the electrode in the appropriate area yielded reliable recordings from all healthy preparations.

These units differed from the multimodal interneurons reported in other arthropods<sup>1-3</sup> in that the most effective visual stimulus was to turn the light off. Turning the light on only occasionally, and not always unambiguously, elicited bursts of spikes. We found no auditory responses, as seen in the locust, nor did we find any small field tactile responses such as are seen in decapods. Rather, touch stimuli to a wide area including body and legs gave con-

Fig. 1. Responses of a multimodal interneuron. A-C, Responses to light off after 5, 10, and 30 sec, respectively, of light adaptation; downward deflection of lower beam indicates stimulus. D, Two responses to touch of ipsilateral cercus. E, Two responses to touch of contralateral cercus. F, Response to touch of ipsilateral mesothoracic tarsus. In D-F the lower beam indicates the approximate duration of stimulus, each sweep 2 sec long. Note that unit also fires spontaneously.

sistent results. We were unable to detect differentially coded responses to spatially separated somatic stimuli.

The function of this type of multimodal interneurone is not clear, although these units are by implication involved in "startle" responses<sup>1</sup>. Tactile stimuli which yield bursts of spikes, such as tarsal or cercal touch, cause intact animals to jump. Tarsal touch is more effective than cercal, although we saw no consistent difference in the spike train; by contrast the animal is markedly sensitive to even the gentlest puff of air directed at the cerci. Abdominal and cercal stimuli elicit impulses in the giant fibre system<sup>2</sup>, and it would seem that the activity of giant fibres is transmitted to the brain where it is presumably integrated with other inputs.

Unlike touch, turning the light off caused no discernible behavioural response in our intact animals; if multimodal units are involved in startle reflexes, this is somewhat surprising because these neurones showed consistent bursts when the light was turned off which matched those following touch. Animals did, however, show pronounced responses to an approaching hand. The integration by other units of light off (dimming) with movement may therefore be necessary before impulses are transmitted to lower centres controlling locomotion. In the case of tactile inputs, the lower centres would be stimulated before the multimodal units<sup>3</sup>. In the case of touch, these units are probably activated after a motor response has been triggered, whatever that might mean. An "arousal" system may be indicated, but we have no idea of the nature or location of whatever would be "aroused". The synchronized response to antennal shock seen in cockroach mushroom body<sup>4</sup> may also be relevant to such a system; its latency was considerably longer than the response elicited in giant fibres by the same stimulus.

The second type of multimodal interneurone observed was excited by light on and inhibited by light off and abdominal movements (Fig. 2). Similar units have been reported only from moth protocerebrum<sup>5</sup>. The light responses of these neurones, however, duplicated those of the "sustaining units" reported from cricket brain<sup>6</sup>. These responses were the following: (i) a transient rise in frequency as the light intensity increased by increments, (ii) a maintained steady frequency positively correlated with light intensity, (iii) a transient decrease in frequency when light was dimmed, and (iv) total cessation of activity when the light was turned off. In addition, the cockroach multimodal units were inhibited when the animal raised and extended the abdomen; other abdominal movements and all tactile stimuli were ineffective except when the

stimuli caused the abdominal movements described. These multimodal interneurones are undoubtedly homologous with the sustaining units of the cricket, for they are similar both in their response and in their anatomical location in tracts running from the optic nerve toward the midline of the brain. Inhibition thus appears to take place somewhere in the optic stalk.

Units detecting static and transient functions of light intensity are an obvious necessity for visual systems, and it is not surprising that they have been found in the cockroach. What is not obvious *a priori*, however, is the inhibition of such units by movements of the abdomen.

We are not sure what the function of this inhibition is. It is, however, well known that in arthropods impulses arising from somatic proprio- and mechano-receptors enter the optic stalk<sup>1,7</sup>. Our results are indirect evidence, at least, that some of the fibres involved may have an inhibitory function.

### Daily and Tidal Components in the Persistent Rhythmic Activity of the Crab, *Sesarma*

In intertidal organisms the rates at which various physiological functions proceed are often related to the state of the tide. In a habitat in which environmental conditions change so drastically with the ebb and flow of the tidal waters, this is not particularly surprising. What is remarkable is that the rate of many of these functions continues to vacillate in approximate synchrony with the tide when organisms are removed to non-tidal, constant conditions in the laboratory. These persistent vacillations are referred to as tidal or bimodal lunar day rhythms. By way of example, persistent tidal rhythms have been described for oxygen consumption in crabs<sup>1</sup>; vertical migrations of planarians<sup>2</sup> and diatoms<sup>3</sup>; colour change in crabs<sup>4</sup>; spontaneous activity in crabs<sup>5,6</sup>, amphipods<sup>7,8</sup>, and fish<sup>9</sup>; and filtration rate in mussels<sup>10</sup>.

Some investigators have reported that in addition to a lunar day rhythmic component in a particular activity of the organism, a 24 h component was present simultaneously<sup>11,12</sup>. Enright<sup>13,14</sup> discredited these earlier claims of dual rhythmic components and stated that there are "... no convincing demonstrations that any organism simultaneously shows both an endogenous tidal and an endogenous circadian rhythm". Since then, other investigators, working on a variety of organisms, have reported what appear to be dual rhythmic components in their results<sup>15-18</sup>, while others, who have specifically looked for such a feature, have found no period which approximates 24 h associated with the tidal rhythms they were investigating<sup>7-10</sup>. In the work reported here, the spontaneous locomotor activity of the intertidal grapeoid

Fig. 2. Continuous record of multimodal interneurone inhibited by abdominal movements. Downward arrow indicates beginning and upward arrow cessation of movement.

crab, *Sesarma reticulatum*, was examined, and clear out rhythmic components of approximately 24 and 24.8 h were found in the locomotor activity.

Crabs were collected from their burrows in the region of the Marine Biological Laboratory, Woods Hole, Massachusetts, and placed in individual actographs, in constant darkness, and a constant temperature of 20° C. After 10–15 days in the actographs, the conditions became foul and the crabs became abruptly inactive or died. Entire series of crabs were therefore replaced at intervals of about 2 weeks. Actograph movements were recorded on an Esterline-Angus event recorder, and the activity of as many as ten crabs could be monitored simultaneously. More than 12,500 "crab-hours" of data went into the investigation reported here.

Over a period of 2 months, five groups of crabs were investigated, and a population average obtained for each hour. As a means of graphic presentation, a method used previously<sup>14</sup> was again utilized. In brief, an average hourly activity rate was calculated for each day of the investigation. Each day was then represented on a graph as an unshaded horizontal bar, and all hourly activity values equal to, or greater than, the daily mean were represented by black squares and plotted with respect to their proper temporal position within the bar. The net result was that minor fluctuations in the activity pattern were "filtered out" and do not appear on the graph, while the times of maximal activity are emphasized by the black squares dispersed along an otherwise unshaded bar. Results on consecutive days were plotted one beneath the other; and the completed graph is shown in Fig. 1. (It should be emphasized that this method of presentation is used only to produce a graph which summarizes and condenses a great deal of data and brings out major trends in the behaviour of the population.) It is quite clear from

Fig. 1. Consecutive daily activity patterns of a population of *Sesarma reticulatum*. The graph has been duplicated, and the right-hand graph displaced upward by one day, in order to facilitate the visualization of the movement of the tidal peaks across the solar day. Parallel, oblique lines superimposed over the figure represent the mid-point of daily high tides. Dashed lines represent mechanical failures of the recording system. The entire crab populations were replaced on July 5, 18 and 29, and August 10.

Fig. 2. Dual components in the persistent rhythmic activity of *Sesarma reticulatum*. Mean solar day rhythm is indicated by open circles; the time scale on the abscissa is pertinent only for this rhythmic component. Solid circles represent the bimodal lunar day rhythmic component. Maxima in this rhythm correspond to the times of high tide (mid-points of high tide are indicated at the top of the figure).

Fig. 1 that most of the daily activity was concentrated between 1800 and 0400 h, there being a strong tendency to activity between 1800 and 2400 h—indicating the presence of a persistent nocturnal, 24 h rhythm in the results.

There are also short "bursts" of activity which occur progressively later each day. They tend to scan across the figure at a rate of roughly 50 min/day, providing visible confirmation of the presence of a tidal component in the activity pattern. The parallel oblique lines superimposed over the figure represent the midpoint of high tides in the natural habitat of the crab, and show that the crabs continue to time their running activity so that a relatively constant fraction of it corresponds with the times of high tide in nature.

The same graphical method was used with the records of each individual crab used during the 2 month investigation, and the same general dual component rhythmic pattern was apparent in each, though usually not as distinctly as when the results were lumped together. It was therefore felt best to present the overall trend of the population in a single figure.

Fig. 1 emphasizes the stability of the period length of both the rhythmic components in the results. Given this criterion—as outlined by Enright<sup>14</sup> and Mercer<sup>17</sup>—one can justifiably construct "form-estimate curves" for the 24 h and 24.8 h components. All the results collected were included in the construction of these curves.

A mean solar day curve was obtained by averaging all the values obtained, in each hour, for the 30 day period from June 23 to July 22, and again—separately—for the second 30 day period between July 23 and August 22. When a 30 day period is used, every phase of the lunar cycle has scanned the hours of the solar cycle once, therefore randomizing the contribution the former makes to the latter. The two average daily curves are seen in Fig. 2. The forms of the two curves are slightly different, but the amplitudes are identical; both emphasize a strong peak of

nocturnal activity. It must be remembered that these curves were obtained by summing five separate groups of crabs. While this is not ideal, it is inevitable because the crabs do not survive for more than a fortnight.

To construct a mean lunar day curve the hourly relationship of consecutive days was realigned so that the hour of lunar zenith on one day was lined up directly beneath the hour of lunar zenith on the next (that is, the results were organized into a lunar day relationship) and corresponding hours of the lunar day summed and averaged for the two monthly periods. With each 30 days of results realigned in this manner, every day of the solar day rhythm is made to scan the hours of the lunar day cycle once, now randomizing the effect of the solar day. The resulting mean lunar day curves are seen in Fig. 2. The phase relationship and form of the two curves are virtually the same, but the amplitude of the curve for June 23 to August 22 is only 58 per cent that of the previous months. The average hourly activity for the second 30 day period was also reduced, dropping from 3.21 to 2.59 major movements/h.

It is quite obvious, therefore, that at least in some intertidal organisms a single rhythmic process may be a montage of approximate 24 h and 24.8 h components. From an ecological viewpoint, one might logically expect to find these two elements co-existing in the rhythms of truly intertidal organisms, because the major environmental factors effecting changes in the physiology of such organisms are imposed on them in these two frequencies. While it is quite clear that some organisms with tidal rhythms lack an associated approximate 24 h component, it may well be that, when more detailed investigations are made of the tidal rhythms of other organisms, they too will demonstrate the presence of the additional second frequency.

I thank Gary Tabor for technical assistance.

## IMMUNOLOGY

### Amino-terminal Amino-acid Sequences of Human Plasma 3S $\gamma_1$ -Globulin and Carbonic Anhydrase B

THE 3S  $\gamma_1$ -globulin of normal human plasma<sup>1</sup> is known to possess chemical and physicochemical properties that are very similar to those of carbonic anhydrase B of human erythrocytes<sup>2,3</sup>. The amino(N)-terminal amino groups of both proteins appear substituted and that of carbonic anhydrase B was reported to be acetylated<sup>4</sup>. To obtain evidence for the identity of these two proteins and to elucidate further their primary structure, the N-terminal

amino-acid sequence of human 3S  $\gamma_1$ -globulin and carbonic anhydrase B was investigated.

Both proteins were analysed by the same procedure and yielded essentially identical results. Protein (105 mg) was dissolved in 20 ml. of water, the pH adjusted to 8.0 and the resulting solution incubated at 70° C for 20 min to denature the protein. After digestion with pronase, the N-terminal acidic peptide fraction which formed was isolated as reported before<sup>4</sup>. The amino-acid composition of this fraction (Table 1) suggested that the N-terminal peptides of both proteins probably consist of 1 mole each of aspartic acid, serine, proline and alanine and that pyroglutamic acid can be excluded as N-terminal amino-acid.

The peptide fraction was resolved into six components by high voltage paper electrophoresis in pyridine-acetate buffer, pH 3.5 (ref. 5). The chief component seemed to be a homogeneous tetrapeptide considering its amino-acid composition (1 mole each of aspartic acid, serine, proline and alanine), and was recovered in an amount corresponding to 0.6 mole/mole of 3S  $\gamma_1$ -globulin and 0.7 mole/mole of carbonic anhydrase B, respectively. The smaller recovery of the tetrapeptide as well as the relatively larger quantities of impurities in the acidic peptide fraction (Table 1) derived from the 3S  $\gamma_1$ -globulin are the result of the presence in this protein preparation of  $\kappa$ - and  $\lambda$ -determinants<sup>6</sup>.

The presence of an acetyl residue as the blocking group of the N-terminus of the tetrapeptide was established by hydrazinolysis<sup>7</sup> (100° C for 17 h) and, after removal<sup>8</sup> of excess hydrazine *in vacuo* at 0° C, by chromatography of the residue. Several appropriate reference substances (Fig. 1a) were used to identify this residue, the amount of which was estimated by comparing the intensity and the size of the spot obtained with those of known amounts of the pure acetylhydrazine and was found to be approximately 1 mole/mole of protein.

The C-terminal amino-acid of the tetrapeptide (0.24  $\mu$ mole) was determined by hydrazinolysis according to Bradbury<sup>9</sup>. After dinitrophenylation the formed dinitrophenol-amino-acid was extracted by Akabori's method<sup>10</sup> and subjected to paper chromatography. Aspartic acid (0.6 mole/mole of peptide) was the sole DNP-amino-acid found.

Table 1. AMINO-ACID COMPOSITION OF THE N-TERMINAL PEPTIDE FRACTION DERIVED FROM 3S  $\gamma_1$ -GLOBULIN AND CARBONIC ANHYDRASE B

Amino-acid	3S $\gamma_1$ -Globulin (mole/mole of protein)	Anhydrase B (mole/mole of protein)
Aspartic acid	0.80	0.95
Serine	0.70	0.82
Threonine	0.13	—
Glutamic acid	0.20	0.10
Proline	0.63	0.95
Glycine	0.25	0.16
Alanine	0.76	0.96

For the complete elucidation of its amino-acid sequence, the peptide (0.2  $\mu$ mole) was partially hydrolysed<sup>1</sup> with 1 normal sodium hydroxide at 30° C and for 40 h, neutralized and dinitrophenylated. The DNP-derivatives were chromatographed to yield five compounds (Fig. 1b). The relative position on the chromatogram, the  $OD_{254}/OD_{280}$  ratio and absorption maximum of each DNP-derivative (Table 2) indicated that compounds 3, 4 and 5 were serine, proline and alanine, respectively, that compound 1 was a mixture of DNP-aspartic acid and a DNP-prolylpeptide in equimolar ratio and that compound 2 was a DNP-peptide without N-terminal proline<sup>11</sup>. Further, the N-terminal amino-acid of compounds 1 and 2 proved to be aspartic acid (DNP-proline is very unstable) and serine, and the non-N-terminal amino-acids aspartic acid and proline, respectively. It might be concluded from these data that compound 1 consisted of DNP-aspartic acid and DNP-proline-aspartic acid and compound 2 was DNP-serine-proline. The great stability of N-acetyl-alanine and certain other N-acetyl amino-acids<sup>12</sup> to mild alkaline hydrolysis explained the small recovery of free

Table 2. SOME PROPERTIES OF THE DNP-AMINO-ACIDS AND DNP-PEPTIDES OBTAINED BY PARTIAL ALKALINE HYDROLYSIS OF THE TETRAPEPTIDES OF 3S  $\gamma_1$ -GLOBULIN AND CARBONIC ANHYDRASE B

DNP-compounds	Maximum absorption (m $\mu$ )	OD <sub>290</sub> OD <sub>280</sub>	Recovery (mole/mole of tetrapeptide)	Relative positions of the amino-acids and peptides in the tetrapeptide	Comments
1	368	0.81	0.40	Aspartic acid	C-terminus
4	385	1.15	0.40	Proline-aspartic acid	The tetrapeptide contained 1 mole of aspartic acid, proline, serine and alanine
2	353	0.56	0.04	Proline	
3	360	0.61	0.36	Serine-proline	
5	360	0.59	0.40	Serine	Substituting amino group of N-terminus
Additional constituent	—	—	0.08	Alanine	
			1.0	Acetyl	

Fig. 1. The amino-terminal amino-acid sequence of human plasma 3S  $\gamma_1$ -globulin and carbonic anhydrase B.

alanine. These findings showed that acetyl-alanine is located at the N-terminus of the tetrapeptides.

This investigation reveals that the amino-acid sequence of the tetrapeptide isolated from both the 3S  $\gamma_1$ -globulin and carbonic anhydrase B is acetyl-ala-ser-pro-asp, and that this peptide represents the N-terminus of both proteins. Thus, the chief component of the plasma 3S  $\gamma_1$ -globulin appears identical with erythrocyte carbonic anhydrase B.

We thank P. O. Nyman, University of Göteborg, Sweden, for the carbonic anhydrase B. This work was supported by grants from the US National Science Foundation and the National Institute of General Medical Sciences, US Public Health Service.

### Purification and Characterization of Carcino-embryonic Antigens of the Human Digestive System

In previous studies from this laboratory, at least two common tumour-specific antigens, or antigenic determinants, were demonstrated to be present in adenocarcinoma of the human colon<sup>1</sup>. Subsequent investigations demonstrated identical antigens in all malignant tumours of the endodermally derived epithelium of the gastrointestinal tract, liver and pancreas, as well as in

foetal gut, liver and pancreas obtained between two and six months of gestation<sup>2</sup>. These carcino-embryonic antigens (CEA) were absent from all other normal, malignant or otherwise diseased adult tissues and all other foetal tissues tested. It was suggested that the carcino-embryonic antigens may represent cellular constituents which are repressed during the course of differentiation of the normal epithelium of the digestive system and reappear in the corresponding malignant cells by a process of derepressive dedifferentiation. Preliminary investigations with tumour tissue extraction in 0.6 molar perchloric acid led to the conclusion that the CEA were protein-polysaccharide

complexes, and immunological data suggested that the tumour-specific antigenic determinants contained carbohydrate components<sup>1,3</sup>.

The purpose of the present investigation was to attempt to purify and characterize the chemical composition of the CEA found in a single autopsy specimen of a histologically confirmed colonic carcinoma which had metastasized to the ovary. A metastatic rather than a primary tumour was selected in order to obtain a large mass of tumour material from a single source.

The presence of CEA activity in the initial homogenate and at each stage of the purification procedure was determined by precipitin-inhibition and direct Ouchterlony testing against specific anti-CEA antiserum<sup>2</sup>.

The 500 g specimen of tumour tissue was homogenized and then extracted in an equal volume of 1.2 molar perchloric acid. After dialysis against distilled water, the active supernatant was lyophilized and further purified by paper block electrophoresis and then column chromatography on 'Sephadex G-200'. Ultra-violet spectrophotometry at 254 m $\mu$  during the chromatographic procedure gave rise to three zones (Fig. 1). Lyophilization of the antigenically active eluate, which was confined to the first zone, yielded 25 mg of powdered material, representing 0.005 per cent of the initial wet weight of tissue.

Initial ultracentrifugation analysis of the purified CEA was complicated by the presence of a soluble, nitrogen-free, glucose polymer contaminant from the 'Sephadex' gel which sedimented at 2.4S. Complete removal of the contaminant was accomplished only by washing the 'Sephadex G-200' with large volumes of buffer under suction in a sintered glass funnel. Repeat ultracentrifugation

Fig. 1. 'Sephadex G-200' chromatography of the CEA preparation following extraction in 0.6 M perchloric acid and separation by paper block electrophoresis. The shaded area indicates the zone containing the CEA activity.

Fig. 2. Ultracentrifugal analysis of the purified CEA preparation. A single peak was obtained at 5.1S.

Fig. 3. Immunoelectrophoretic pattern of the perchloric acid extract of the tumour homogenate (CEA), and this extract further purified by paper block electrophoresis and column chromatography on 'Sephadex G-200' (purified CEA), against untreated rabbit anti-human colonic cancer antiserum.

gation studies following removal of the contaminant revealed the presence of a single peak at 5.1S which contained all the antigenic activity (Fig. 2).

Immunoelectrophoresis of the purified CEA preparation was performed against untreated rabbit anti-human colonic cancer antiserum<sup>1</sup>. The result obtained was that of a single precipitin band in the  $\beta$ -globulin region (Fig. 3). This finding indicates the relative immunogenic purity of the preparation, but does not completely exclude the presence of additional weak antigens in the purified CEA preparation.

A 10 mg sample of purified CEA was prepared for qualitative carbohydrate analysis by hydrolysis in a sealed 'Pyrex' tube for 16 h in 0.5 normal hydrochloric acid at 100° C. Analysis of the hydrolysate by descending paper chromatography revealed the presence of galactose, glucose, mannose, fucose and glucosamine. (Some or all of the glucose may have represented contamination from the 'Sephadex' column.) The presence of sialic acid in the purified CEA was demonstrated by the use of Ehrlich reagent according to the technique described by Werner and Odén<sup>2</sup>.

A 5 mg sample of purified CEA was prepared for amino-acid analysis by a modification of the technique described by Lea and Schon<sup>3</sup>. Analysis of the hydrolysate was performed in an amino-acid analyser. The purified CEA was found to contain measurable quantities of eight amino-acids. There were relatively high proportions of tyrosine and lysine with respect to the other six amino-acid residues. If the tyrosine content of CEA is given a

relative value of 1.0, the relative values of the remaining amino-acid residues are approximately as follows: lysine 0.8, aspartic acid 0.3, threonine 0.25, serine 0.3, glutamine 0.3, glycine 0.3, and alanine 0.15.

Further investigations now in progress in our laboratory are designed to compare the quantitative chemical composition of the CEA from a number of different human digestive system cancers with comparable fractions from a variety of other human tissues, both normal and cancerous.

This work was supported by research grants from the National Cancer Institute of Canada, Toronto, Ontario; and the Cancer Research Society, Inc., Montreal, Quebec. The analysis of the amino-acid preparation and the ultracentrifugation studies were performed with the co-operation of Dr A. H. Schon, Department of Chemistry, McGill University.

### Detection of Genetic Antigens utilizing Gamma Globulins coupled to Red Blood Cells

THE genetic antigens of the human gamma globulin system have been detected primarily by a haemagglutination inhibition reaction<sup>1</sup>. Anti-Gm or Inv antibodies from rare human sera are generally utilized in the test system together with Rh positive red cells coated by specific anti-Rh antibodies. This method has proved of considerable value but also has a number of important limitations. The finding that primate and rabbit antisera appropriately absorbed can replace the rare human sera eliminated one major defect in the system<sup>2,3</sup>. A second major problem has been the dependence on selected anti-Rh antibodies containing the specific genetic antigen required for red cell coating. This problem has been brought to the fore in recent attempts to discover new genetic markers for the subgroups of IgG as well as for IgM and IgA. In many instances incomplete anti-Rh coats could not be found which contained the specific type of protein required. For example, the Gm (n) antigen<sup>4</sup>, which was delineated recently for the IgG2 class<sup>5</sup> of proteins, could only be determined by relatively insensitive precipitation procedures because no suitable anti-Rh coat could be found.

The present investigations were undertaken in an attempt to develop a typing system using red cells coated directly with isolated globulins containing the required genetic antigen. Some efforts in this direction have been made previously utilizing the tanned cell technique<sup>6</sup>. This work was confirmed, but the tanned cell procedure proved inferior for these delicate genetic systems. Considerably greater success was achieved through direct coupling of myeloma proteins to the red cells by the bis-diazotized benzidine (BDB) technique.

Isolation of myeloma proteins and macroglobulins by zone electrophoresis, pepsin-digestion of gamma globulin and isolation of heavy and light chains were performed as previously described from this laboratory<sup>6</sup>. Anti-Gm antisera were obtained by immunizing rabbits, monkeys

\* The nomenclature used for the heavy chain subgroups of IgG is that recently adopted by a subcommittee of WHO: IgG1 (We or  $\gamma$ 2b); IgG2 (Ne or  $\gamma$ 2a); IgG3 (Vi or  $\gamma$ 2c); IgG4 (Ge or  $\gamma$ 2d).

and baboons with isolated myeloma proteins or macroglobulins or respective heavy chains. After absorption with human sera negative for the corresponding genetic factor, the antisera showed specific anti-Gm reactions in agglutination and inhibition tests with reference anti-Rh coated red cells<sup>2</sup>. Anti-Gm (g) 3978<sup>7</sup> and anti-Gm (a) 3070 of human origin were also used.

A stock BDB solution was prepared, and stored as described by Gordon *et al.*<sup>8</sup>. The optimal proportion of BDB and antigen used for coating of a certain amount of red cells was determined for each new batch of BDB stock solution by titrations. The following procedure was generally adopted. To 0.06 ml. of three-times washed and packed<sup>9</sup> human O red cells, 0.06 ml. BDB solution (stock solution diluted 1/15 in 0.15 molar phosphate buffer pH 7.3) was mixed. After 2 min, 1–1.5 mg of isolated gamma globulin (for example, 1 c.c. of a 0.1 per cent solution) was added and the mixture left at room temperature for 15 min. The cells were then washed four times in phosphate buffered saline pH 7.3, resuspended to a 1 per cent dilution, and used the same day that they were coated.

Tests and readings with the coated red cells were routinely done by tube technique, but the slide modification could also be used, as described for the anti-Rh system<sup>6</sup>. When properly coated, the red cells showed no agglutination in saline or in normal human or rabbit serum diluted 1/5, but gave a high titre against standard anti-Fr II antiserum. The coating by this BDB method was performed in excess of antigen. The supernate fluid could be used again for coating of red cells; it retained specific inhibitory capacity, and further addition of antigen did not strengthen the reaction of the coated cells. On the other hand, decreasing amounts of antigen for coating quickly lead to weaker or non-reacting red cells. These findings also compared well with those using reference anti-Rh antibodies<sup>9</sup>.

Table 1. TEST SYSTEMS USING RED CELLS COATED WITH MYELOMA PROTEINS OF DIFFERENT GENETIC TYPES AND ABSORBED PRIMATE AND RABBIT ANTISERA GIVING SPECIFIC AGGLUTINATION

Red cells coated with:	Specificity and titre of absorbed antiserum*
Myel. Ke Gm (a+)	Anti-Gm (a)† 1/300
Myel. Fe Gm (b+)	Anti-Gm (b) 1/32
Myel. Gr Gm (f+)	Anti-Gm (f) 1/50
Myel. Vi Gm (g+)	Anti-Gm (g)† 1/128
Myel. Ne Gm (n+)	Anti-Gm (n)† 1/64

\* The titre given is the working titre utilized and not the highest titre showing specificity.

† Primate antisera.

For Gm testing, myeloma proteins of Gm (a), Gm (g), Gm (f), Gm (b) and Gm (n) type were coupled to red cells by BDB and used with respective anti-Gm antisera (Table 1). In the Gm (a), Gm (f) and Gm (b) tests different myeloma proteins were selected for coating than those used for immunization, thus eliminating the problem of individual specific determinants<sup>6</sup>. For Gm (g) and Gm (n) typing the homologous system was used and the individual specific antibodies were absorbed out by the respective myeloma proteins digested by pepsin (refs. 4 and 7, and results to be published).

Table 2 illustrates typical inhibition reactions for the different systems as utilized for the Gm typing of sera. Gm (a+) or Gm (f+) sera inhibited the Gm (a) and Gm (f) systems in dilutions of 1/640. Gm (g), Gm (b) and Gm (n) inhibition was in the range of 1/40 to 1/160. In contrast, negative sera diluted 1/2 did not inhibit. Inhibition with myeloma proteins also gave identical results and showed similar inhibitory capacity whether anti-Rh coated or myeloma protein coated cells were used. A protein, positive for a certain Gm factor, showed inhibition in concentrations down to 4–16 µg/ml. Gm typing of human sera was done at the dilution 1/10 and gave clear readings with negative controls. Fifty selected Caucasian and Negro sera were studied by the BDB technique and in all instances complete concordance with the anti-Rh

Table 2. INHIBITION REACTIONS FOR Gm TYPING USING RABBIT AND PRIMATE ANTIBODIES AND RED CELLS COATED BY MYELOMA PROTEINS

Typing system	Phenotype of inhibitor serum*	Degree of agglutination at progressive dilutions of inhibitor						No inhibitor
		2	10	40	160	640	2,560	
Gm (a)	a + g + f - b - n -	0	0	0	0	0	2	2
	a - g - f + b + n +	2	2	2	2	2	2	
Gm (f)	a - g - f + b + n +	0	0	0	0	0	2	3
	a + g + f - b - n -	2	3	3	3	3	3	
Gm (b)	a - g - f + b + n +	0	0	0	2	3	3	3
	a + g + f - b - n -	3	3	3	3	3	3	
Gm (g)	a + g + f - b - n -	0	0	1	3	3	3	3
	a - g - f + b + n +	3	3	3	3	3	3	
Gm (n)	a - g - f + b + n +	0	0	0	Tr	3	3	3
	a + g + f - b - n -	2	3	3	3	3	3	
	a - g - f + b + n +	2	3	3	3	3	3	
	a + g + f - b - n -	2	3	3	3	3	3	

\* The underlined letters designate the specific antigen tested.

system was obtained. The Gm (n) system was studied in particular detail. Seven Gm (a + g + f - b -) sera were Gm (n-). Of fifteen Gm (a + g + f + b +) sera, six were Gm (n+) and nine Gm (n-). Of eighteen Gm (a - g - f + b +) sera, sixteen were Gm (n+) and two Gm (n-). The Negro sera were Gm (a + g - f - b +) and Gm (n-). The several Gm (f + n -) sera were of special interest and were tested at least twice. They gave a clear negative pattern in the Gm (n) test. All the results were the same as for the precipitation system<sup>4</sup>.

Red cells coated with pooled gamma globulin were also used for the test systems involving the principal subgroup of gamma globulin and worked well for Gm (a) and Gm (f). Gamma globulin fragments and chains could be utilized as coating agents and isolated heavy chains of the γG3 myeloma protein Vi were advantageously used for red cell coating and typing for Gm (g). Anti-Gm factors from human sera specifically agglutinated the myeloma protein coated red cells. Red cells coated with Gm (g) myeloma protein Vi were agglutinated by anti-Gm (g) 3978 which was used at the dilution 1/32 for typing both myeloma proteins and human sera. Corresponding results were obtained with the Gm (a) myeloma protein Ke and anti-Gm (a) 3070. The system was also utilized for Inv (1).

The myeloma proteins thus coupled to red cells by BDB showed a specificity and sensitivity very similar to the system utilizing anti-Rh antibodies. Although the agglutinates dispersed somewhat more readily than those with anti-Rh coated cells, the agglutination was strong and could be read after centrifugation within minutes. This new method offers a valuable supplement to the anti-Rh antibodies used for coating. The main importance is the extension to globulins of classes or subclasses where the anti-Rh system cannot be used. More than one hundred high titre incomplete anti-Rh sera were tested without finding anti-Rh antibodies which revealed IgG2, IgG4, IgA or IgM antigenic characters. All these classes of immune globulins could be coated, however, on red cells which then gave agglutination reactions with rabbit and primate antisera which were class specific. In the case of the IgG2 class, the additional Gm (n) specificity was readily demonstrated and utilized for genetic typing.

We thank Dr J. K. Moor-Jankowski for certain of the primate antisera to myeloma proteins. This work was supported by a grant from the US Public Health Service.

# Autotransplantation and Homotransplantation of Thyroid Gland in the Hamster Cheek Pouch

EXPERIMENTAL transplantation of the thyroid gland has been widely investigated<sup>1,2</sup>. As a rule autotransplantation of the adult thyroid is easily attained, but positive results with homotransplantation in laboratory animals (mammals) are sometimes achieved only after additional treatment with corticosteroids<sup>3,4</sup> or after implantation in the anterior lye chamber<sup>5,6</sup>, brain or, especially in the case of the guinea-pig<sup>7</sup>, in the testes.

In 1951, Lutz *et al.*<sup>8</sup> first used the hamster cheek pouch for transplantation of tumours. The cheek pouch is a favourable immunologically tolerant site not only for homo and heterotransplantation of tumours, but also for such normal tissues as skin<sup>9</sup>.

Here we report the survival of thyroid tissue implanted in the cheek pouch. This indicates the acceptability at this site of a highly specialized organ.

Fifty-eight male and female non-inbred Syrian hamsters (*Mesocricetus auratus* Waterhouse, 1839) were used. The donors and recipients were of the same sex and about 3 months old. Table 1 shows the experimental conditions and the results. The cheek pouches of the animals with transplants were checked weekly, and the animals were killed between the forty-fifth and ninety-third days after transplantation. Transplants were only considered to have survived if certain features were present: viable transplants are commonly reddish and surrounded by a set of vessels. They have a typical appearance under the microscope (Fig. 1) and neither degenerative parenchymal changes nor inflammatory reactions are evident.

Table 1. EXPERIMENTAL GROUPS AND RESULTS AFTER TRANSPLANTATION OF A HALF THYROID GLAND IN CHEEK POUCH OF THE SYRIAN HAMSTER

Group	No. of animals	Treatment before transplantation	Mode of transplantation	No. of takes Positive	Negative
I	13	Thyroidectomy (surgical only)	auto	12	1
II	16	Thyroidectomy (surgical or after 500 $\mu$ c. <sup>131</sup> I treatment)	homo	13	3
III	19	Non-treated	homo	4	15

The follicles of the transplants from groups I and II were smaller than those of group III, while in the normal gland *in situ* the larger follicles were distributed at the periphery. The cells of the first two groups were cuboidal or cylindrical but in group III they were lower. The size and appearance of the follicles and cells depend to some extent on the

Fig. 1. Microscopic structure of a gland 45 days after homotransplantation. (Haematoxylin and eosin,  $\times c. 40$ .)

Fig. 2. Autoradiograph from the same gland ( $\times c. 70$ ).

mechanical pressure exerted by walls of the pouch. A colloid was abundantly present in the follicles from group III, while in groups I and II it was not homogeneous after staining with eosin and periodic acid-Schiff, and many vacuoles were visible at the internal cell apex. The nuclei of the cells were dark and had a coarse chromatin network. About 10–20 per cent of the follicular and inter-follicular cells have a clearer cytoplasm and nucleus.

We thyroidectomized some of the animals from group III several days before killing them in order to verify that pituitary extract stimulated the transplants. It was found that the latter are more like the transplants of groups I and II than others.

The animals examined had been injected intraperitoneally with 2  $\mu$ c. of <sup>131</sup>I sodium iodide 6 h before they were killed. After fixation paraffin slides of their thyroid glands were mounted on strips of Kodak 'AK 10' stripping films.

Under the experimental conditions used, inorganic iodine-131 was taken up only by the tissues from groups I and II, that is, in the animals deprived of thyroids *in situ*. Accumulation of radioactive iodine was high and irregular in different follicles (Fig. 2).

These results show that the cheek pouch of the Syrian hamster is a convenient site for thyroid transplantation. A much better survival of homotransplants was observed in thyroidectomized animals. This supports Halstead's views<sup>10</sup>, which have been contested in recent years by some authors<sup>11</sup>.

## PATHOLOGY

**Effect of Cyclophosphamide, 6-Mercaptopurine or Methotrexate on the Furth Rat Leukaemia**

In the course of experiments designed to test the effect of new cytotoxic chemicals on the Furth leukaemia in the rat, we decided to examine some clinically established cancer chemotherapeutic agents. Because we believed that the action of the agents might have an immunological basis, each was tested alone and in combination with Freund's complete adjuvant.

The Furth leukaemia used came, in 1964, from the Chester Beatty Research Institute which, in turn, received it from Dr Jacob Furth in 1957. The special strain of Wistar rats had the same history and have been maintained as a closed colony since they were received in Leeds. The leukaemia was passed through male rats by the intraperitoneal injection of 750,000 leukaemia cells in citrate saline. This leukaemia kills its hosts 9–16 days after inoculation. The total white cell count immediately before death always exceeds 100,000 and is usually 150,000 to 200,000 cells/mm<sup>3</sup>. The liver is haemorrhagic and enlarged, often with a ruptured capsule. The spleen is enlarged and friable, with prominent Malpighian bodies. The mediastinal, para-aortic, lumbar and mesenteric lymph nodes are massively, and the axillary and inguinal glands slightly, enlarged. The killing time of this leukaemia has previously been delayed by treatment with *o*-merphalan<sup>1</sup> and, to a lesser extent, with CB1718 (hydantoin-5-spiro-2'-(*x*-di-2'-chloroethylamino)-1', 2', 3', 4'-tetrahydronaphthalene)<sup>2</sup>.

Young adult rats (120–150 g) of either sex were maintained on 'Oxo' diet 41B and water *ad libitum*. Freund's complete adjuvant, 'Endoxana' cyclophosphamide, 6-mercaptopurine and methotrexate were administered as shown in Table 1.

The results (Table 1) show that Freund's complete adjuvant induced no increase in survival, compared with

the control animals, and that 6-mercaptopurine or methotrexate increased the survival time by about 60 per cent, which is of marginal significance. The animals treated with cyclophosphamide, however, showed, when the experiment was terminated, a mean survival of 112 days, while two animals were still alive at 210 days. Freund's complete adjuvant increased this survival to a mean of 170 days, with eight rats still alive at 210 days ( $P=0.012$ ) (ref. 3).

A further four experiments were carried out to confirm and amplify this result. In four of the five experiments, cyclophosphamide induced a considerable lengthening of life. Freund's complete adjuvant, by itself, had no effect on the leukaemia. When the cyclophosphamide was injected shortly after the rats were inoculated with the leukaemia (Table 2, experiments 1–3) a further marked increase in survival resulted with Freund's complete adjuvant. On the other hand, when the cyclophosphamide treatment was delayed until the total white cell count was beginning to rise, that is, until the position approached that of a clinically detectable leukaemia, Freund's complete adjuvant had no significant effect (Table 2, experiments 4, 5).

The fact that cyclophosphamide alone, or, more often, in combination with Freund's complete adjuvant enabled rats to survive for more than 200 days, instead of the normal 9–16 after inoculation, led us to attempt to determine whether or not they still carried the leukaemia. To this end, the ten survivors in experiment 1 (Table 2) were treated as follows: three (one of which had originally received cyclophosphamide alone) were killed and examined; a similar group was re-inoculated with 750,000 cells from the Furth leukaemia, and the remaining four were re-inoculated and treated with cyclophosphamide on days 1 and 4, and Freund's complete adjuvant on days 8, 11 and 12 thereafter.

Two of the three rats killed at 210 days after the initial treatment had total white cells counts of 22,300 and 18,100 cells/mm<sup>3</sup> respectively. No abnormality apart from

\* Rat surviving. † Died without leukaemia on naked eye examination. ‡ From Table 1.

bronchiectasis was seen at post-mortem examination. Histological examination confirmed the bronchiectasis and showed reactive hyperplasia and mild fibrosis in the associated mediastinal lymph nodes. There was no evidence of leukaemia. The third rat had a slightly raised total white cell count of 32,000 cells/mm<sup>3</sup> (polymorphs 35 per cent, lymphocytes 55 per cent, monocytes 5 per cent, eosinophils 3 per cent and basophils 2 per cent) and post-mortem examination showed severe bronchiectasis and a large pulmonary abscess, together with slight enlargement of the para-aortic and mediastinal lymph nodes. Histological examination of these nodes showed, in addition to inflammatory changes, areas in which the normal lymph node structure was replaced by sheets of leukaemic cells, indicating that this animal still had a residual leukaemia. At post-mortem, blood from these three rats was withdrawn and, in each case, an amount containing 750,000 white cells was injected into two further rats. These six animals are still surviving 69 days afterwards. The group of three rats which were reinoculated with the Furth leukaemia died at 13, 14 and 14 days—a survival which is similar to that of a group of untreated rats inoculated with the same blood (15 days). The reinoculated rats which received both cyclophosphamide and Freund's complete adjuvant are still alive 69 days after the introduction of the leukaemia.

The fact that one of the three rats which were killed 210 days after inoculation showed microscopic evidence of leukaemia is clear evidence that treatment with cyclophosphamide and Freund's complete adjuvant does not completely eradicate the leukaemia. This is supported by the observation in experiment 2 (Table 2) that rats treated in the same way died of leukaemia after 201 and 205 days. Their leukaemia was demonstrated by examination with the naked eye. Nevertheless, the increase in survival brought about by the treatment is impressive. The effect of the antimetabolites 6-mercaptopurine and methotrexate is in no way changed by the use of Freund's complete adjuvant. On the other hand, the effect of the cytotoxic cyclophosphamide is enhanced by the use of the adjuvant.

These results are difficult to explain. They could be accounted for by the suggestion that the cyclophosphamide destroys a high proportion of the leukaemic cells by direct cytotoxic action and by stimulating an immunological attack against the products of the chemical reaction between it and various cellular constituents. The action of Freund's complete adjuvant would then be to heighten this immunological attack and to reduce further the number of fully viable leukaemic cells. This property of the adjuvant is effective only when the number of leukaemic cells is small for a period shortly after inoculation but is, presumably, swamped when the leukaemia begins to develop. The alternative explanation, that Freund's complete adjuvant acts by enhancing an immunological attack on the cellular constituents of the Furth leukaemia itself, is rendered less likely by the failure to demonstrate a second set response when rats which had survived for more than 200 days after the first inoculation were reinoculated.

We thank Dr Jean A. S. Pringle for the histological examinations, Mr G. Littlewood for maintaining and treating the animals and Dr D. B. Clayson for help in the preparation of this paper.

## "Enteque Seco", Calcification and Wasting in Grazing Animals in the Argentine

"ENTEQUE SECO" is the name given to a wasting disease of grazing animals frequently encountered in the central eastern and south-eastern areas of the province of Buenos Aires and which is a cause of considerable economic loss to livestock producers.

The disease was first reported in 1898 by Lignières<sup>1,2</sup>, who thought it might result from chronic pasteurellosis. Eckell *et al.*<sup>3</sup> have discussed in some detail the various factors involved in its aetiology, and Arnold and Bras<sup>4</sup> drew attention to the similarity between enteque seco and Naalehu disease in Hawaii and Manchester wasting disease in Jamaica.

Enteque seco seems to be confined to the poorer, swamper areas of the province of Buenos Aires on well defined soil types<sup>5</sup>. It is most often seen in Aberdeen Angus, Shorthorn and Hereford breeding cows, because these are the animals most commonly run in the affected areas. Bulls, heifers, and steers can also be affected, however, and other breeds of cattle such as the Friesian are known to be susceptible. Sheep and horses are not often found with the disease, but lesions have been found at necropsy in both species<sup>2,6</sup>.

The incidence of the disease is difficult to assess accurately, but some herds have been found with as many as 10 per cent of animals affected. The incidence of the disease is known to vary with the year, the season and the site.

The earliest symptoms are a stiffened and painful gait with a progressive loss of weight and symptoms of ill-thrift and emaciation. If the animals are removed in the early stages from the affected areas they recover quickly, but they may eventually die if they are left.

In advanced cases the radiocarpal joints thicken and become stiff and the distal joints become very straight. In more advanced cases the joints cannot be extended completely, the thoracic limbs bow outwards and the animals tend to "buckle over" and walk with an arched back, carrying the weight on the forepart of the hooves (Fig. 1). The shoulders appear stiff and deformed and the articulation of the forequarters is distinctly abnormal. The head is usually carried very erect.

Such animals are often excitable and tire easily if they are made to exercise. They may show symptoms of acute cardiac and pulmonary insufficiency. If they are removed from the affected areas at this stage the severe stiffness and deformity are not lessened, but the wasting is usually stopped and the animals may gain weight if moved to good pasture. Practical experience has shown that these animals are not suitable breeders and they are usually culled and slaughtered.

Fig. 1. A young Aberdeen Angus cow with advanced enteque seco showing typical stance of severely affected animals. The stiffened, bowed forelimbs and deformed shoulder with the weight taken on the forepart of the hooves are characteristic. Note also erect carriage of head and dull, wasted appearance.

At necropsy the animals show a widespread metastatic calcification of the vascular system and the soft tissues. The heart and aorta invariably show the most marked effects (Fig. 2). The left auricle and ventricle are invariably more affected than the right parts of the heart.

Calcareous deposits are often found in the lungs, particularly around the periphery of the diaphragmatic lobes (Fig. 3). These lesions appear to develop later than those in the vascular system: the heart and the vessels are frequently found damaged without any effect on the lungs, but lung damage is never found alone.

The cartilage of the appendicular skeleton is always eroded in advanced cases, and the bearing surfaces of the leg joints take on a very worn appearance, being almost completely devoid of cartilage. The bearing surfaces are also often eroded.

The liver and spleen appear to remain unaffected. The kidneys are sometimes affected by diffuse damage, with some calcification of the pelvic region<sup>7</sup>.

Ruksan *et al.* have shown that animals pasturing in areas known to produce the disease have high concentrations of calcium and inorganic phosphorus in the blood<sup>8</sup>. Concentrations of these two elements ranging from 25 to 50 per cent above normal are often found. These blood concentrations change within 48–72 h when the affected animals are moved to good pasture. We think that these high concentrations of calcium and phosphate on the blood are the underlying cause of the calcification found in affected animals. No infectious processes appear to be involved, and the symptoms are similar to those found in vitamin D intoxication<sup>7</sup>.

There is no evidence from soil analyses to throw light on the change of blood calcium and inorganic phosphate<sup>8,10</sup>. Also, the concentrations of calcium and phosphorus in bulk forage samples from affected areas seem to be essentially normal<sup>9</sup>.

A mixed forage sample from an area prone to entequ seco was recently shown to be able to raise the concentration of calcium and phosphorus in the blood of 2 year Aberdeen Angus heifers when given in the form of air-dried and milled material by way of rumen fistulae. As little as 1 kg of the material, given as a single dose, increased the calcium and phosphorus concentrations for 4–5 days<sup>11</sup>. When the samples of the original plant material were ashed, the activity was lost. Much of the activity could be recovered in the aqueous fraction after extraction with water, and remained in the supernatant after extraction with 80 per cent alcohol<sup>12</sup>. On the basis of these findings, it was thought that a specific principle or principles was implicated which was soluble in water and organic, non-protein and non-allergenic in nature.

Fig. 2. Massive calcification of the aorta and heart from an affected animal. The enlarged and heavily mineralized chordae tendineae are a quite typical feature.

Fig. 3. The cut edge of a diseased lung showing advanced calcification. The latter is usually most prominent around the periphery of the diaphragmatic lobes.

Fig. 4. *Solanum malacoxylon* Sendtner. Balcarce, Province of Buenos Aires.

Thirty-six species were found in the sample<sup>13</sup>, and seven were collected for further investigation. *Solanum malacoxylon* Sendtner (probably conspecific with *Solanum glaucum* Dun.<sup>14,15</sup>) was later found to be capable of reproducing the results found in fistulated animals dosed with the whole sample. Extracts of *Solanum malacoxylon* in water are also active. As little as 5 g of dry matter given as a single dose by stomach tube can produce changes in the calcium and phosphorus in the blood of 900 lb. heifers for several days. A similar effect can be produced in 100 lb. Romney ewes by as little as 0.5 g<sup>11,12</sup>. These experiments were carried out using leaves and stems of *S. malacoxylon* (about one-third leaf, two-thirds stem, on a dry matter basis). Later work has shown that almost all the toxin is contained in the leaves, so that the amount of leaf material alone required to produce the effect can be assumed to be even less.

*S. malacoxylon* is distributed over the area in which the disease is known to occur, such anomalies as may exist being explicable on the basis of the transfer of animals between areas (which may occur frequently), variations in animal management or in the toxicity and palatability of the plant. The plant is generally fairly unpalatable, but this does not preclude its ingestion in small amounts by animals grazing freely, as has been found in the field<sup>16</sup>.

Although many questions remain to be answered, some points are clear. The majority of plant species growing in entequ seco areas are common species with wide distributions in areas outside those in which the disease is known

to occur. A number of indigenous species which might be thought to contribute to the disease have been shown to be unable to raise the concentrations of inorganic phosphorus and calcium in the blood. The fact that the careful removal of all traces of *S. malacozylon* from representative samples of mixed herbage results in the complete inactivation of the sample would seem to show that only *S. malacozylon* is involved in causing the disease<sup>12</sup>.

The hypothesis that *S. malacozylon* is the only species involved in causing enteque seco is being tested further in experiments that are now in progress.

### Demonstration of Copper and Acid Phosphatase Activity in Hepatocyte Lysosomes in Experimental Copper Toxicity

EXCESSIVE amounts of copper accumulate within the tissues in Wilson's disease (hepatolenticular degeneration). Cirrhosis is believed to be an inevitable consequence of chronic copper toxicity<sup>1</sup>. Attempts to produce equivalent hepatic dysfunction and cirrhosis in experimental animals by copper poisoning have been unsuccessful, however<sup>2</sup>.

In Wilson's disease, high concentrations of copper have been localized to acid phosphatase-rich hepatocyte lysosomes by combining electron probe microanalysis with enzyme cytochemistry<sup>3</sup>. In rats poisoned with copper the metal has been demonstrated by light microscopy staining methods<sup>4-6</sup> in pericanalicular granules which resemble, in appearance and cytoplasmic location, lysosomes visualized in acid phosphatase preparations. In experimental copper toxicity, however, acid hydrolase activity and copper have not been visualized in the same preparation and in the same granules. It seemed worth while to find out whether the copper granules in these animals also showed acid hydrolase activity and were in fact lysosomes<sup>7,8</sup>.

This was accomplished by staining for both copper<sup>9,10</sup> and acid phosphatase activity<sup>11</sup> on the same section, with fairly specific procedures.

Specimens of liver, obtained from rats given drinking water containing 0.25 per cent copper sulphate for several months, were fixed overnight in cold 4 per cent neutral formaldehyde containing 1 per cent calcium chloride. Frozen sections (10 $\mu$ ) were incubated for acid phosphatase activity in the naphthol AS-TR phosphate-hexazotized pararosaniline medium of Barka and Anderson<sup>12</sup>, washed

thoroughly and then immersed very briefly in Timm's silver nitrate-hydroquinone solution<sup>9,10</sup>. Timm<sup>9,10</sup> has shown that in tissues with very high concentrations of copper the metal may be stained black by simply immersing a section in a solution of silver nitrate and hydroquinone. This reaction is less sensitive but more specific than the more common silver sulphide procedure for visualizing copper<sup>3,5,9,10,12</sup>. In the latter procedure the metal is first sulphated by exposing the tissue to hydrogen sulphide. When the sulphide step is omitted the silver solution does not make iron visible, iron being the only other metal likely to be present in liver in large enough quantities to stain. This solution, prepared just before use, is made up of one part of 5 per cent silver nitrate and 5 parts of a mixture of 2 g hydroquinone and 5 g citric acid in copper-free distilled water. The doubly stained sections were dehydrated and mounted in 'Permount'.

Black grains of silver, marking the sites of copper, were deposited on pericanalicular cytoplasmic granules which had been stained red by virtue of their acid phosphatase activity, identifying the granules as lysosomes<sup>7,8</sup> (Fig. 1). Difficult to demonstrate in a black and white photomicrograph, the combination of red and black was striking when viewed in the microscope. Not all lysosomes contained stainable copper. The silver solution did not alter the acid phosphatase reaction product, but fewer copper granules could be seen in sections that had been incubated for enzyme activity. Similar cytoplasmic granules were made visible by staining unincubated sections with rubeanic acid, considered to be a specific stain for copper<sup>13</sup>. Normal rat liver did not stain with the silver solution and rubeanic acid.

Although copper, in high concentrations, is localized to hepatic lysosomes in Wilson's disease<sup>3</sup> and in animals intoxicated with copper, the absence of cellular necrosis and cirrhosis in experimental copper poisoning<sup>2,4,5</sup> suggests that an additional factor is responsible for liver damage in the human disorder. The possibility must be considered that some unknown factor in Wilson's disease may damage the lysosomal membrane, leading to release

Fig. 1. Frozen section of rat liver poisoned with copper. This specimen contained, 1245 $\gamma$  of copper/g wet weight of liver. Normal concentration is approximately 10 $\gamma$ . The section was incubated for acid phosphatase activity<sup>11</sup> and then stained for copper. The black stain marks the site of copper and is deposited on many of the less darkly stained (red on the slide) lysosomes made visible by the acid phosphatase procedure. This is difficult to demonstrate in a black and white micrograph, but both stains are evident in some granules (arrows). ( $\times$  2,000.)

of copper into the cytoplasm and cell death. At present, we have no evidence that such a release takes place.

This work was supported by a special fellowship and a grant from the US Public Health Service. I thank Dr G. J. A. Van der Hamer, who kindly supplied the experimental animals and performed the copper assays.

## BIOCHEMISTRY

### Dietary Starch, Dietary Sucrose and Hepatic Pyruvate Kinase in Rat

It has been pointed out<sup>1</sup> that a low activity of hepatic pyruvate kinase (ATP-phosphotransferase *EC* 2.7.1.40) favours gluconeogenesis, and a high activity favours lipogenesis from oxidizable substances. These experiments with rats showed that the activity of the enzyme was

Table 2. PYRUVATE KINASE ACTIVITY OF RAT LIVER

Activity as $\mu\text{moles/min/g}$ fresh weight ( $\pm S.E.$ )						
Diet	No. of rats	Days on diet	Age at start (days)	Weight at start (g)	Weight at end (g)	Pyruvate kinase activity
60 per cent sucrose	6	10	39	93	134	102.7 $\pm$ 15.4
60 per cent starch	6	10	39	95	134	20.2 $\pm$ 2.1
Carbohydrate-free, I	5	10	39	96	142	10.4 $\pm$ 1.3
Carbohydrate-free, II	4	10	39	97	149	7.6 $\pm$ 0.9
Total carbohydrate-free	9	10	39	97	145	9.2 $\pm$ 0.9
72 per cent sucrose	5	98	28	42	283	63.0 $\pm$ 5.8
72 per cent starch	5	98	28	41	281	28.1 $\pm$ 3.8

rapidly affected by alterations in the amount of carbohydrate in the diet, being highest when the diet contained 80 per cent carbohydrate (as sucrose), less when it contained 55 per cent carbohydrate (mostly as starch) and least when it contained no carbohydrate.

In view of recent findings that levels of blood lipids and amounts of adipose tissue in rats are changed when the dietary carbohydrate is changed from starch to sucrose<sup>2</sup>, we have measured the activity of hepatic pyruvate kinase in rats given diets with the one or the other carbohydrate at the same levels.

Male hooded rats of the Lister strain were used for the experiments. The composition of the diets is shown in Table 1. The enzyme activity was estimated by the method of Bücher and Pfeleiderer<sup>3</sup>, except that the concentration of adenosine diphosphate was increased to  $1.3 \times 10^{-3}$  molar. Preliminary experiments with weanling rats showed that purified diets with 60 per cent sucrose gave an enzyme activity three or four times higher than that given by diets with 60 per cent starch. The effect was seen after 3 days on the diet, and there was only a

Table 1. COMPOSITION OF DIETS  
Male hooded rats were given these diets, and water, *ad libitum*. Quantities are in g/km

	Carbo- hydrate- free, I	Carbo- hydrate- free, II	Sucrose 60 per cent	Starch 60 per cent	Sucrose 72 per cent	Starch 72 per cent

slight increase in the enzyme activity on either diet after another seven days.

The results of two further experiments are shown in Table 2. In each instance, the difference in activity of pyruvate kinase between the dietary treatments is highly significant ( $p < 0.001$ ). The highest level of activity was found in rats that were put on the experiment when they were 39 days old, and fed the purified diet with 60 per cent sucrose for 10 days. The results of this experiment parallel closely those<sup>1</sup> in which the diet with 80 per cent sucrose gave an enzyme activity about ten times that given by carbohydrate-free diets. Our results with the starch-containing diet suggest, however, that the intermediate level found by these authors with diets containing 55 per cent carbohydrate as starch was due more to the type of carbohydrate than to its quantity.

The difference in pyruvate kinase activity in rats fed sucrose or starch for 98 days, though still highly significant, was less than in rats fed for only 10 days. It is possible that this was caused by the differences in the type of dietary fat, but it may be that the animals gradually adapt to the differences in carbohydrate.

Differences in enzyme activity produced by the different levels of fat in the two diets free of carbohydrates were not significant at a level of  $P = 0.05$ . We might expect significant differences with greater differences in fat content; as it is, the differences are in the expected direction in view of the higher ketogenic potential of the diet higher in fat.

The observation<sup>1</sup> was confirmed that a diet with carbohydrate produces a higher activity of hepatic pyruvate kinase in rats than a diet free from carbohydrate. We must add, however, that the activity of the enzyme also depends on the type of dietary carbohydrate, as sucrose produces a considerably higher activity than does starch.

### Milk and Serum Iron and Iron-binding Capacity in the Rabbit

IN the course of a study of protein metabolism during lactation in the rabbit it was found that iron added to the whey fraction of rabbit milk changed the colour from yellow to bright pink. The colour change was similar to that observed when iron is added to the serum iron-binding protein, transferrin. It suggested that rabbit milk contains a high concentration of similar protein. This would be a most unusual finding, and it prompted an investigation of the iron concentration and iron-binding capacity of rabbit whey and rabbit serum during lactation.

Samples of blood and milk were obtained at intervals during lactation from the first to about the thirtieth day of lactation. The blood, obtained by incision of the marginal ear vein, was allowed to clot and the serum was used for measurements of iron and total iron-binding capacity (TIBC)<sup>1</sup>. Milk was expressed with care from the mammary glands to avoid contamination with iron. Part was used to estimate the whole-milk iron concentration<sup>2</sup>. The remainder was centrifuged at 4° C for 1 h at 25,000*g*, and the clear layer between fat and casein removed and recentrifuged as before. The resulting clear whey was used to determine the total iron-binding capacity by the same method as used for serum. Six non-lactating mature female rabbits were used to obtain control serum iron and iron-binding capacity values.

The results are summarized in Fig. 1. The serum iron concentration was high in the first few days of lactation, but after about the fourth day it fell to the same level as in the non-lactating rabbits, and remained at this level for the rest of lactation. The serum TIBC remained relatively constant during lactation at a significantly higher level than in the non-lactating animals. In the milk the iron concentration was similar to that of serum for the first 3 weeks of lactation, but thereafter it increased and was much higher than in serum in samples collected between the twenty-fifth and thirty-second days of lactation. The milk TIBC was about four times as high as the serum value for the first 3 weeks of lactation, and increased after that to even higher levels.

When the proteins of rabbit whey were compared with those of serum by paper electrophoresis<sup>3</sup> it was found that the principal whey protein had a similar electrophoretic mobility to the  $\beta$ -globulin of serum (Fig. 2). Quantitative

Fig. 1. Serum and whey iron concentration (Fe) and total iron-binding capacity (TIBC) during lactation in the rabbit. Each point is the mean of six rabbits at the time indicated except for the last point which is the mean of twelve rabbits sampled between days 25 and 32 of lactation. The mean serum values of six non-lactating rabbits are also shown. The vertical lines represent  $\pm$  one standard error of the mean.

Fig. 2. Paper electrophoresis of rabbit serum (S) and rabbit whey (M), and autoradiographs obtained by the addition of iron-59 to the serum and whey.

analysis of the electrophoretic strips showed that the  $\beta$ -mobility component represented about 50 per cent of all the whey protein. The fact that the major whey protein fraction was indeed an iron-binding protein was shown by autoradiography. Serum and whey to which iron-59 chloride had been added in amounts less than the latent iron-binding capacity were fractionated by paper electrophoresis and exposed before staining to X-ray film. The autoradiographs so obtained showed that all of the radioactive iron was bound to serum  $\beta$ -globulin and to the whey protein with similar electrophoretic properties (Fig. 2).

The high values found for serum TIBC in the latter half of pregnancy in the rabbit<sup>4</sup> continue during lactation. The high serum iron value found during the first few days of lactation results from a sudden rise at the time of parturition from the low concentration observed towards the end of pregnancy<sup>4</sup>. This rise may be the result of the sudden cessation of iron loss to the foetuses. With the onset and increase in lactation during the first few days after parturition, loss of iron into the milk may replace that to the foetuses, so that the serum iron concentration falls somewhat. Although the milk iron concentration is not high, it represents a daily loss of about 500  $\mu$ g iron, because it has been found that rabbits in this colony usually secrete 150–200 ml. of milk per day. This is a considerable amount of iron to a small animal like the rabbit and must result in greatly accelerated plasma iron turnover and iron absorption.

The milk TIBC and electrophoresis results show that a major protein component of rabbit milk whey is an iron-binding protein with similar properties to those of serum transferrin. The significance of this finding is uncertain. It seems unlikely that the milk protein is necessary for the transfer of iron to the milk. Other animals with much lower concentrations of iron-binding protein in the milk secrete iron into the milk in higher concentrations than does the rabbit. In the rat<sup>5</sup> and a marsupial, the Rottneest Island quokka<sup>6</sup>, iron is secreted into the milk in concentrations greatly exceeding the serum iron concentration and the whey iron-binding capacity. In both these species, whey iron-binding capacity values are much lower than in the rabbit, although the iron-binding capacity of the rat whey rises towards the end of lactation as it does in the rabbit. The milk iron-binding protein of the rabbit may correspond with the red protein, or lactoferrin<sup>7–11</sup> of human and bovine milk, but is present in much higher concentrations. Indeed, if it is assumed that the rabbit protein has a molecular weight similar to transferrin (90,000) and binds two atoms of iron per molecule, the whey concentration may be calculated as 2 g/100 ml. earlier in lactation, later rising to 2.5 g/100 ml. With the secretion of 150–200 ml. milk of which about two-thirds is whey,

2 g or more of the iron-binding protein may be secreted each day.

### Effect of Actinomycin on Protein Synthesis by Lymphocytes

WHEN human lymphocytes are incubated with phytohaemagglutinin (PHA), an extract of *Phaseolus vulgaris*, they transform into blast cells, which enter cell division<sup>1,2</sup>. This process is accompanied by a rise in the rate of synthesis of RNA and protein<sup>3,4</sup> and by changes in the types of RNA synthesized<sup>5,6</sup>. Actinomycin, which acts primarily by inhibiting RNA synthesis, is known to inhibit protein synthesis secondarily in many tissues, but the synthesis of some proteins has been found to be resistant to actinomycin<sup>7</sup>. This communication reports the effect of actinomycin on protein synthesis by lymphocytes.

DL-1-<sup>14</sup>C-leucine (32 mc./mmole) was used in these experiments. Solid PHA was reconstituted in tissue culture medium TC199, and used at a concentration of 0.015 ml./ml. of lymphocyte suspension.

Lymphocytes were prepared from human blood by sedimentation with gelatine<sup>8</sup>. The supernatant was diluted with 2 vol. of medium TC199 to give a suspension containing  $0.6-1.2 \times 10^6$  lymphocytes/ml. Cultures of 0.5 ml. were prepared and incubated as previously described<sup>4</sup>. At the times indicated in Fig. 1 the culture medium was replaced by fresh medium containing <sup>14</sup>C-leucine (1  $\mu$ Ci./ml.) and with or without actinomycin D (10  $\mu$ g./ml.).

Cultures prepared in this way contained variable numbers of cells other than lymphocytes, mainly granulocytes. In some experiments granulocytes and monocytes were removed by passing the gelatine supernatant through a cotton wool column, as described by Lamvik<sup>9</sup>. The yield (50-75 per cent) and purity (95-100 per cent) of lymphocytes obtained in this way were similar to those obtained by Lamvik. The lymphocytes were collected by gentle centrifugation and suspended in medium composed of 25 per cent inactivated bovine serum and 75 per cent TC199 to give a concentration of  $0.4-0.9 \times 10^6$  lymphocytes/ml.

Incorporation of <sup>14</sup>C-leucine was assessed as described previously<sup>4</sup>. In some cases (Fig. 1b and 1d), however, the membranes on which the radioactive precipitate had been collected were washed with 2 per cent (v/v) acetic acid, placed in a vial, dried, and covered with toluene scintillator containing 2,5-diphenyloxazole (3.5 g/l.) and 1,4-bis-(5-phenyloxazol-2-yl) benzene (50 mg/l.). The radioactivity was determined in a Nuclear-Chicago scintillation spectrometer, at an efficiency of about 50 per cent. The efficiency using the original method was about 20 per cent. Four or five replicate cultures were used for each measurement.

Fig. 1a shows that the incorporation of <sup>14</sup>C-leucine by freshly prepared cultures is almost completely inhibited after incubation with actinomycin D for 3 h. Very similar

results were obtained using the purified lymphocytes prepared with a cotton wool column (Fig. 1b). After incubation with PHA for 1 or 2 days (Fig. 1c) the incorporation of <sup>14</sup>C-leucine was still markedly inhibited by actinomycin, but a proportion was found to become less sensitive to the antibiotic. Incorporation was, for example, proceeding at 15-30 per cent on the control rate 5-7 h after the addition of actinomycin. This effect was not dependent on the addition of PHA, because it was also observed when cultures were incubated without PHA for 1 or 2 days before the addition of actinomycin (Fig. 1d).

The decrease in the sensitivity of protein synthesis to actinomycin does not result from a lesser sensitivity of RNA synthesis to the action of the drug. Incubation of lymphocyte cultures alone does not result in any detectable decrease in the sensitivity of <sup>3</sup>H-uridine incorporation to actinomycin while incubation with PHA causes a significant increase. Actinomycin at this concentration (10  $\mu$ g./ml.) inhibits <sup>3</sup>H-uridine incorporation by cultures without PHA by 85-90 per cent, while <sup>3</sup>H-uridine incorporation by cultures which have been incubated with PHA for 2 days is inhibited by 97 per cent.

Actinomycin was not found to increase the rate of loss of <sup>14</sup>C-leucine which had been incorporated into protein. When lymphocytes which had been incubated with <sup>14</sup>C-leucine were transferred to a medium containing either an excess of cold leucine or cycloheximide, an inhibitor of protein synthesis, the presence of actinomycin in the second medium did not increase over a period of 7 h the slow loss of <sup>14</sup>C-leucine observed.

It has been suggested that the effect of actinomycin on protein synthesis may be affected by the glucose concentration in the incubation medium<sup>10</sup>. In these experiments

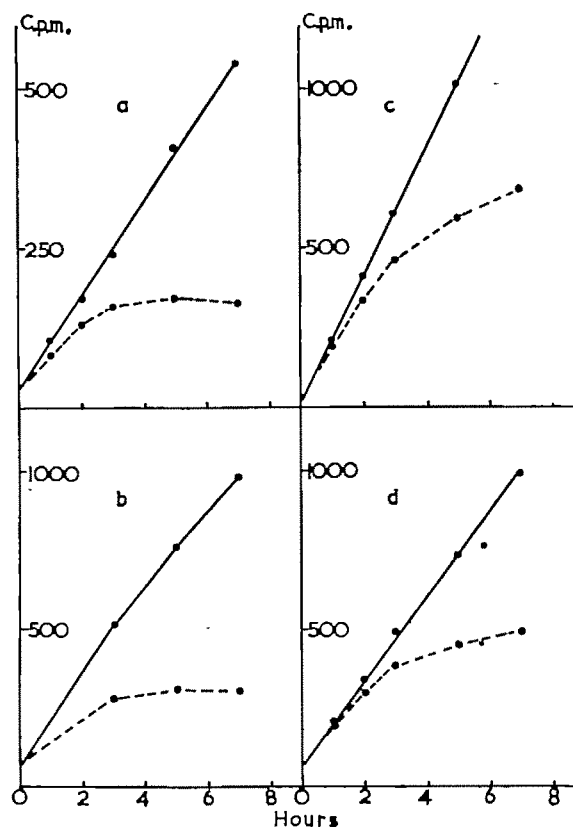

Fig. 1. Effect of actinomycin on incorporation of <sup>14</sup>C-leucine. Cultures of 0.5 ml. were preincubated with or without PHA as indicated below. The medium was then replaced by medium containing <sup>14</sup>C-leucine (1  $\mu$ Ci./ml.) and with or without actinomycin (10  $\mu$ g./ml.) and incubation continued at 37° C. ●—●, Control; ○—○, actinomycin. a, No preincubation; b, cultures prepared by the cotton wool column method; c, cultures preincubated with PHA for 22 h; d, cultures preincubated alone for 21 h.

the glucose concentration at the time of addition of actinomycin was the same in all experiments (5.5 mmolar).

Actinomycin has itself been claimed to cause the degradation<sup>11</sup> or stabilization<sup>12</sup> of RNA, but other authors have concluded that actinomycin does not affect the stability of rapidly labelled or messenger RNA (refs. 13-17). The possibility that actinomycin affects protein synthesis in some way other than through inhibition of RNA synthesis cannot be ruled out<sup>18</sup>. It seems likely, however, that most of the functional messenger RNA of freshly isolated lymphocytes is degraded within 8 h of the addition of actinomycin, while after incubation of lymphocytes *in vitro* a proportion becomes more stable.

I thank the Science Research Council, the Medical Research Council and the British Empire Cancer Campaign for support, and Dr A. Korner for advice and encouragement.

## Vectorial Metabolism

THEORIES of active biological transfer have been discussed in the light of the Curie principle<sup>1,2</sup>, which forbids the combination of a scalar force, such as the chemical affinity of a reaction, with a vector flux such as the diffusion flux of a solute<sup>3</sup>. In active transfer, solutes are transferred against their gradients of electrochemical potential by means of energy derived from metabolism. It has usually been stated that direct thermodynamic cross coupling between a chemical reaction and the flux of an active transfer cannot occur<sup>3</sup> and, instead, the chemical reaction is supposed to modify the electrochemical potential of the transferred solute which then diffuses spontaneously.

Active transfer systems ( $\text{Na}^+ + \text{K}^+$ -activated ATPases) have been described in which the transfer seems to be obligatorily coupled with the chemical reaction supplying the energy<sup>4</sup>, and the concept of "vectorial metabolism" has been proposed<sup>5</sup> to describe this obligatory association. The ion transfer appears to be an integral part, not a consequence, of the chemical reaction and could not therefore result from a restriction imposed by the structure of a membrane on the free diffusion of a reactant or a product (see ref. 1). This association between a chemical reaction and an ion transfer would seem to violate the Curie principle. A theory of direct cross coupling between a chemical reaction and a diffusion process has been put forward<sup>6</sup>, but has been severely criticized<sup>1,3</sup>. The present author has suggested<sup>7</sup> that direct coupling between a chemical reaction and a diffusion process is permissible if the transition-state theory of Eyring and Eyring<sup>8</sup> is employed to formalize active transfer. The relation

between this suggestion and the proposal of vectorial metabolism is discussed here.

In transition-state theory<sup>8</sup>, the course of a chemical reaction is denoted by the passage of reactants and products over a saddle-point on a potential energy surface along a single co-ordinate, the "reaction" co-ordinate; and diffusion processes also take place along a single co-ordinate. Similarly, the direct coupling between chemical reactions and diffusion processes suggested by the present author<sup>7</sup> was postulated to occur in a system described by one co-ordinate, in which reasons were given for allowing the vectors which represented the diffusion flux and force to degenerate<sup>9</sup> to scalar quantities.

According to Guggenheim<sup>10</sup> the reaction co-ordinate can be given a geometrical meaning, that is the passage of individual molecules along a reaction co-ordinate involves an actual translocation in space. In isotropic systems, these individual molecular displacements cancel each other out, so that there is no net transfer of reactants or products in any particular direction. In anisotropic systems, on the other hand, if a preponderance of the individual reaction co-ordinates is orientated in one particular direction in three-dimensional space, net fluxes of reactants and products in that direction will automatically result. It is therefore suggested that the occurrence of vectorial metabolism depends on the anatomical properties of the system rather than on the nature of the coupling between chemical reactions and translocations.

This concept can be illustrated by a discussion of some enzyme reactions. NAD and NADP-dependent dehydrogenases show stereochemical specificity and can be classified into two groups according to which side of the pyridine ring the hydrogen atom from the substrate is attached<sup>11</sup>. It has been suggested that a pyridine nucleotide molecule forming a "sandwich" between the protein apoenzymes of two dehydrogenases could transfer hydrogen atoms from the substrate of one to the substrate of the other through a molecular rearrangement without disrupting the "sandwich"<sup>12</sup>. If the pyridine nucleotides form part of a membrane, a net flux of hydrogen atoms across the membrane will occur if all the pyridine rings are facing the same way. No net flux of hydrogen atoms in any one direction will occur if the reaction is proceeding in a homogenate in which the pyridine rings are randomly orientated. Irrespective of whether the reaction is taking place in a membrane or in a homogenate, the passage of reactants along the reaction co-ordinate includes a translocation of hydrogen atoms in one particular direction relative to the pyridine ring.

The action of ( $\text{Na}^+ + \text{K}^+$ )-dependent ATPases exhibits a stereospecificity which resembles that shown by the pyridine nucleotide enzymes. ATPase activity in homogenates of membranes is dependent on sodium and potassium ions without causing a net flux of either ion in any particular direction, whereas in intact membranes the sodium and potassium ions must be on opposite sides of the membrane for hydrolysis of ATP to occur and the ions are transferred in opposite directions across the membrane<sup>13</sup>. Here, the passage of reactants along the reaction co-ordinate includes translocations of sodium and potassium ions in opposite directions relative to the active site. When a majority of the reaction co-ordinates are orientated normal to the surface of the membrane, ATP-dependent fluxes of sodium and potassium ions across the membrane will be observed. When the active sites, and therefore the reaction co-ordinates, are randomly orientated in a homogenate, no net transfer of ions in any direction will be observed.

The Curie principle, which is concerned with the symmetry or asymmetry of systems<sup>1</sup>, is not violated in vectorial metabolism because, by the principle of entropy balance<sup>14</sup>, the degree of asymmetry of the system as a whole is either unchanged or reduced at the end of the chemical reaction. The coupling between active transfer and a chemical reaction is discussed elsewhere in relation

to the irreversible entropy production within the whole system<sup>1</sup>.

The allosteric rearrangement postulated by Jardetzky<sup>12</sup>, like the change-of-state reaction postulated by Vidaver<sup>14</sup> to account for facilitated diffusion, assumes that the complex between the membrane component and the transferred species undergoes a configurational rearrangement which results in the translocation of the transferred species. As pointed out elsewhere<sup>7</sup>, this type of phenomenon is included in the entropy of activation when transition-state theory<sup>8</sup> is used to formulate a theory of active transfer. If one of the reactants is a macromolecule, the site of the chemical reaction may be separated spatially from the site of the coupled diffusion, as in the allosteric model of Jardetzky<sup>12</sup>. It would not be surprising to find that some of the reactant species were spatially separated from each other during a chemical reaction when three or more reactant species are forming a transition-state.

## Observations on the RNA Metabolism of Leukaemic Cell Cultures

MORE than half the RNA synthesized in mammalian cells is ribosomal and transfer RNA. This RNA is rich in guanine (G) and cytosine (C) and is polymerized by a DNA-dependent RNA polymerase<sup>1,2</sup>. Conversely, the RNA synthesized in mammalian cells infected with cytotoxic single-stranded RNA viruses, such as poliovirus and B<sub>19</sub> virus, is predominantly viral RNA. This RNA is rich in adenine (A) and uracil (U) and is polymerized by virus-induced, RNA-dependent RNA polymerase<sup>3-5</sup>. Cells infected with such viruses also show repression of the synthesis of GC-rich cellular RNA<sup>6,7</sup>. Little is known about the metabolism of RNA in mammalian cells infected with leukaemia viruses. The present study was undertaken to examine some gross characteristics of RNA synthesis in leukaemia cells from

mice in which the leukaemias resulted from infection either with the Rauscher leukaemia virus or with a virus from radiation-induced myeloid leukaemia<sup>10</sup>. Recent investigations have shown that the nucleic acid of the Rauscher virus is single-stranded RNA with about 52 per cent total G+C and a low uridine content<sup>11,12</sup>. The nature of the nucleic acid of the radiation-induced myeloid leukaemia virus is not known.

Myeloid leukaemias and reticulum cell sarcomata were induced in *RF/Urf* mice by injecting the radiation myeloid leukaemia virus or the Rauscher virus, respectively. Primary cultures of normal spleen cells and cultures of the leukaemia cells from grossly infiltrated spleens were prepared by the method of Ginsburg and Sachs<sup>13</sup>. The medium used in all cases was Eagle basal medium containing a four-fold increase in the concentration of essential amino-acids and vitamins, with 20 per cent horse serum. Each of the three cultures was divided into three groups and treated as follows: 1 h after explantation ( $7 \times 10^4$  cells/ml.), actinomycin D (1  $\mu$ g/ml.) was added to one group and puromycin (50  $\mu$ g/ml.) was added to a second group. A third group in each culture remained untreated. 2 h after explantation, all cultures received phosphorus-32 (35–40  $\mu$ Ci/ml.). 5 h after the addition of phosphorus-32, the cells were collected, frozen and the labelled RNA extracted with phenol at 60° C (ref. 14). Specific activities, distribution of phosphorus-32 among the nucleotides, and fingerprint patterns of the labelled RNA were determined as previously described<sup>15,16</sup>.

The labelled RNA from leukaemic cells infected with the Rauscher virus showed a slight average increase in specific activity compared with normal spleen cells (Table 1). Extensive variation in the specific activity of labelled RNA from normal spleen cell cultures was evident, however. In spite of this variation it is obvious that the specific activity of labelled RNA from myeloid leukaemia cells was markedly increased (Table 1). To what extent these increases might reflect differences in mitotic indices has not been determined. None the less, leukaemic cells and normal spleen cells both showed a marked inhibition (85–92 per cent) of RNA synthesis in the presence of actinomycin D, indicating that the RNA synthesized in such cells was predominantly DNA-dependent. This contrasts sharply with the behaviour of cells infected with cytotoxic viruses, in which RNA synthesis is insensitive to actinomycin D (ref. 17). These results also argue against, but do not entirely exclude, the possibility that an RNA-dependent RNA polymerase was responsible for the synthesis of a large portion of the RNA in the leukaemic cells.

Whereas cultures of both normal spleen cells and leukaemic cells resulting from infection with Rauscher virus showed 60–70 per cent inhibition of RNA synthesis in the presence of puromycin, myeloid leukaemia cells under identical conditions showed more than 95 per cent inhibition (Table 1). The reason for such sensitivity to puromycin is not known. It has been reported, however, that the synthesis of ribosomal RNA is preferentially inhibited by puromycin<sup>18,19</sup>. Attempts to repress the development of myeloid leukaemia in infected mice by daily injections of puromycin (100  $\mu$ g/mouse) have been unsuccessful (Teeter and Tyndall, unpublished results). While the effects of puromycin on the synthesis of RNA in the two

‡ Distribution of phosphorus-32 among the nucleotides following alkaline hydrolysis. Average of two experiments.

types of leukaemia cells differ reproducibly, RNA from both types of leukaemia cells is rich in guanine and cytosine as is shown by a high content of total Gp and Cp, as well as by high contents of GpCp and GpApCp oligonucleotides (Table 1). High levels of total G and C in leukaemia spleen cells resulting from Friend virus infection have also been reported<sup>20</sup>.

The synthesis of RNA rich in total Gp and Cp and GpCp and GpApCp oligonucleotides in virus-infected leukaemic cells contrasts sharply with the repression of GC-rich RNA synthesis in cells infected with cytotoxic viruses<sup>21</sup>. The ratio of both GpCp and GpApCp to ApUp oligonucleotides in leukaemic cell RNA is equal to or greater than that in normal spleen cells (Table 1); however, the degree to which the ratio in leukaemic cells differs, if at all, from that of the corresponding normal stem cells cannot be specified. The ratio in leukaemic cells is also greater than that previously reported for HeLa cells and L cells<sup>14,21</sup>. To what degree malignant cells from various sources follow a similar pattern cannot be stated without more extensive investigation. It is noteworthy, however, that Muramatsu and Busch have shown that various cell fractions from Walker rat tumour cells have a higher content of GC-rich RNA than those from corresponding normal liver cells<sup>22</sup>. The contrast between the characteristics of the RNA synthesized in leukaemia cells and that synthesized in cells infected with cytotoxic viruses is not unexpected, considering that cells infected with cytotoxic viruses are degenerative and synthesize predominantly viral RNA, with repression of the synthesis of GC-rich cell RNA. Leukaemic cells, however, are proliferative and apparently synthesize both GC-rich cell RNA and virus RNA. It is interesting to note that polyoma tumour virus, unlike some other DNA-containing viruses, also induces virus and cell DNA synthesis on infection<sup>23</sup>.

This investigation was sponsored by the US Atomic Energy Commission under contract with the Union Carbide Corporation. We thank Dr K. B. Jacobson for his valuable discussions concerning this manuscript.

## DNA and RNA Synthesis and the Formation of Blastogenic Factor in Mixed Leucocyte Cultures

AFTER incubation for several days, cultures of mixed leucocytes from two individuals contain immature mononuclear cells. These cells incorporate thymidine into DNA (refs. 1 and 2). A material which stimulates blastogenesis of allogeneic leucocytes is released into the surrounding medium when human leucocytes are cultured *in vitro*<sup>3-5</sup>. More of this material is released into the medium from mixed leucocyte cultures than from cultures of leucocytes from single donors. This communication reports experiments which were designed to determine DNA and RNA synthesis and the formation of blastogenic factor in mixed leucocyte cultures after various periods of incubation.

The subjects were normal volunteers. An aseptic technique was used throughout the experiments. A leucocyte suspension was prepared as previously described<sup>1</sup>. The leucocytes were washed once with medium 199. The cells were finally resuspended in fresh plasma pooled from several healthy donors, using sufficient to adjust the leucocyte count to between 5,000 and 7,000/mm<sup>3</sup>. The cell suspensions were diluted with medium 199 so that the final plasma concentration was 20 per cent. The mixed cultures contained a 1:1 mixture of cells from two subjects. Unmixed cultures of leucocytes from one of the donors were also established. The cell suspensions were incubated in 17 × 100 mm disposable culture tubes. Mixed or unmixed leucocyte cultures were divided into three groups. The first group consisted of mixed leucocyte cultures. Cell-free culture medium and the ultracentrifuged precipitate were prepared from ten culture tubes in this group, after incubation times of 8, 18, 24, 36, 48, 120, 168 and 240 h. Smears were made from the cells in the cultures at these times and stained with Jenner-Giemsa. Blastogenic activity of these preparations from mixed cultures after these incubation times was assessed as described previously<sup>3</sup> by adding the preparations to leucocyte cultures from a single donor, incubating for 5 days, and measuring the uptake of <sup>3</sup>H-thymidine by the cultures by means of a liquid scintillation counter<sup>6</sup>. The results are expressed as c.p.m./4 × 10<sup>5</sup> cells. The second and third groups consisted of both mixed and unmixed leucocyte cultures. At the same time intervals, <sup>3</sup>H-thymidine (specific activity 5 c./mmole and a final concentration in each culture tube of 1 µc./ml.) was added to two tubes of each culture in the second group. After incubation for 2 h at 37° C, the cells were washed once in cold physiological saline, and then twice in 5 per cent trichloroacetic acid (TCA). DNA was extracted by the Schmidt-Tannhauser technique<sup>7</sup>, except that the concentration of potassium hydroxide was decreased to 0.5 normal. At the same time intervals as those of cultures in the second group, uridine-5-T (specific activity 5 mc./mmole and a final concentration in each culture tube of 1 µc./ml.) was added to two tubes from each mixed and unmixed culture in the third group. After 2 h at 37° C, their RNA was extracted by a slight modification of the Schmidt-Tannhauser technique<sup>8</sup> as previously described. The radioactive content of the DNA or RNA fraction was counted in a liquid scintillation counter. Quenching was measured by an internal standardization method<sup>9</sup> using <sup>3</sup>H-toluene as the internal standard. Quenching was nearly identical for the samples of RNA and DNA. The concentration of the DNA or RNA present in each preparation was determined by measuring the optical density at 260 mµ in a spectrophotometer with a hydrogen lamp. The results are expressed as c.p.m./10 µg of DNA or RNA.

As shown in Table 1, the ultracentrifuged precipitates from mixed leucocyte cultures which had been incubated for 18 h showed slight blastogenic activity. There was a further increase in activity of similar preparations from

Table 1. ELABORATION OF BLASTOGENIC FACTOR IN MIXED LEUCOCYTE CULTURES DURING INITIAL 48 h INCUBATION

Length of initial cultures (source of blastogenic material) (h)	<sup>3</sup> H-thymidine uptake (c.p.m./4 × 10 <sup>4</sup> cells)*	Control cultures (5-day) of unmixed leucocytes

48	2,905 ± 806	1,111 ± 123	1,782 ± 46	1,036 ± 79	(+)

\* Average values obtained from four experiments ± S.D.

† DNA and RNA syntheses were determined by incorporations of <sup>3</sup>H-thymidine and uridine-5-T, respectively. See the method in the text.

‡ Blast transformation was determined in Jenner-Giemsa stained smears independently by two observers and was expressed on an arbitrary scale. —, No large basophilic blast cells were found in smears; +, blast cells were occasionally found in smears.

cultures which had been incubated for 24 h. At this time, RNA and DNA synthesis was the same in mixed leucocyte cultures as in the unmixed control cultures. No evidence of any blast transformation was found in smears from 24 h mixed cultures (Table 2).

The blastogenic activity reached a peak just after 120 h of incubation, but it decreased after 168 h (Fig. 1). The uptake of tritiated thymidine in cultures of leucocytes containing the precipitates from mixed cultures incubated for 120 h was 8,046 (mean from four experiments) ± 1,148 (S.D.) c.p.m./4 × 10<sup>4</sup> cells, while those in leucocyte cultures with the precipitates from 72 h and 168 h mixed cultures were 5,428 ± 135 and 4,302 ± 233, respectively. The blastogenic activity of the cell-free culture medium was determined at the same time intervals as those of the ultracentrifuged precipitate, and the effects of the two preparations were entirely similar. The ultracentrifuged precipitate was more active, however, than the cell-free culture medium.

Fig. 1. DNA and RNA synthesis and formation of blastogenic factor in mixed leucocyte cultures. Each point represents the average value obtained from four experiments. The DNA (O---O) and RNA (x---x) syntheses were determined as described in the text. The activity of the blastogenic factor (●---●) is expressed as the uptake of <sup>3</sup>H-thymidine (c.p.m./4 × 10<sup>4</sup> cells) in 5-day cultures of leucocytes containing 1 ml. of the ultracentrifuged precipitate prepared from mixed cultures after various periods of incubation.

As shown in Table 2, DNA and RNA synthesis began to increase above that of the control cultures only after incubation for 48 h, at which time a few blasts were first seen in the stained smears. As the incubation time of the mixed cultures was prolonged, there was an increase in DNA and RNA synthesis (Fig. 1) and in the amount of blast transformation. DNA synthesis reached its maximum after incubation for 120 h (the uptake of <sup>3</sup>H-thymidine in these cultures was 30,079 (mean) ± 4,901 (S.D.) c.p.m./10 μg DNA), and then continued at this level until 168 h incubation (32,242 ± 7,127 c.p.m./10 μg DNA), after which it decreased (Fig. 1).

The RNA synthesis reached a maximum after incubation for 168 h (Fig. 1). The uptake of <sup>3</sup>H-uridine in mixed cultures incubated for 168 h was 16,539 (mean from four experiments) ± 4,901 (S.D.) c.p.m./10 μg RNA. The radioactive uptakes in mixed cultures incubated for 120 h and 240 h were 10,238 ± 933 and 10,420 ± 943, respectively.

It seems pertinent that significant stimulation occurred in the cell-free medium of 18 h and 24 h mixed cultures before there was any evidence of increased DNA and RNA synthesis and at a time when large basophilic blast cells could not be demonstrated morphologically. It is probable that the blastogenic factor is not produced by the lymphoblastoid cells.

### *In vitro* Inhibition of Erythrocyte Glucose Consumption by Human Growth Hormone

We have found that human growth hormone *in vitro* markedly inhibits the glucose consumption of human erythrocytes. This effect could not be duplicated with growth hormone preparations from the pig, cow or monkey.

Erythrocytes from the heparinized blood of healthy adult males were freed from leucocytes and platelets by centrifuging at 200g for 15 min, followed by aspiration of the plasma and buffy coat. The cells were washed three times in four volumes of 0.15 molar saline and centrifuged at 1,000g after each wash. The supernatant and buffy coat were aspirated after each wash. The washed erythrocytes were incubated in a Krebs-Ringer bicarbonate buffer, pH 7.4, at an adjusted haematocrit of 33 per cent. The erythrocytes were enriched with glucose to a final concentration of 10 mmol/l. Three ml. of this erythrocyte suspension were incubated in a 25 ml. flask for 2 h at 37° C in a metabolic shaker set at 80 oscillations/min. The gas phase was 5 per cent carbon dioxide in air. One of each pair of flasks contained purified human growth hormone (Wilhelmi H.S. 612B) in a final concentration that ranged from 0.5 to 32 μg/ml. The glucose concentration of the incubation mixture was determined at 0, 1 and 2 h by the glucose oxidase method<sup>1</sup>. Duplicate glucose determinations showed variations of less than 2 per cent.

In seven experiments using purified human growth hormone (HGH) at a final concentration of 16  $\mu\text{g/ml}$ , red cell glucose consumption fell 32.9–59.0 per cent, the mean fall being 49.3 per cent (Table 1). A difference in glucose consumption between the control red blood cells and those treated with growth hormone was observed within 15 min and was evident throughout the 2 h incubation period. Glucose consumption remained linear for 2 h in the control flasks and those supplemented with growth hormone.

Table 1. EFFECT OF GROWTH HORMONE PREPARATIONS ON HUMAN RED CELL GLUCOSE CONSUMPTION

Preparation	No. of studies	Concentration ( $\mu\text{g/ml}$ )	Glucose consumption ( $\mu\text{moles/ml RBC/h}$ ) Control (mean)	Glucose consumption ( $\mu\text{moles/ml RBC/h}$ ) +HGH (mean)	Inhibition (per cent)	P
Purified human	7	16	1.61 $\pm$ 0.25	0.81 $\pm$ 0.18	49.3 $\pm$ 9.8	< 0.001
Crude human	13	128	1.56 $\pm$ 0.21	0.66 $\pm$ 0.11	56.6 $\pm$ 4.7	< 0.001
Porcine	3	128	1.71 (1.58–1.83)	1.74 (1.60–1.86)	0.0 (8.9–23.4)	> 0.5
Bovine	5	128	1.43 (1.21–1.71)	1.23 (1.10–1.44)	15.3 (7.9–24.0)	< 0.01
Monkey	3	128	1.49 (1.25–1.69)	1.24 (1.21–1.49)	11.3 (7.9–14.0)	< 0.05

As shown in Fig. 1, the depression in red cell glucose consumption varied with dose over a range from 1 to 32  $\mu\text{g/ml}$ . No effect was observed with HGH concentrations less than 1  $\mu\text{g/ml}$ .

The inhibition of glucose consumption by HGH was not affected by the simultaneous addition of Lilly glucagon-free crystalline insulin in concentrations as high as 2 U/ml.

In experiments in which fructose was used as a substrate, HGH at a final concentration of 16  $\mu\text{g/ml}$  depressed fructose consumption by an average of 44.7 per cent.

Erythrocyte glucose-6-phosphate (G-6-P) and fructose-6-phosphate (F-6-P) concentrations were determined before and after incubation of human erythrocytes with glucose in the presence of 16  $\mu\text{g/ml}$  of HGH for 2 h. In three experiments the erythrocyte G-6-P concentrations before incubation were 8.80, 9.79 and 10.20  $\mu\text{moles/100 ml}$  of erythrocytes. The concentrations of G-6-P in the red cells incubated with HGH rose to 13.70, 14.52 and 15.42  $\mu\text{moles/100 ml}$ , respectively. The concentrations of F-6-P in these same cells rose from values of 2.28, 2.48 and 2.61 to 3.44, 3.57 and 3.90  $\mu\text{moles/100 ml}$ , respectively. The concentrations of G-6-P and F-6-P were unaltered in the erythrocytes incubated without HGH.

The production of carbon-14 dioxide in the red cells remained constant in the presence of HGH, despite a drop in the total glucose consumption (Table 2). Red

Table 2. EFFECT OF HGH ON RED CELL CARBON-14 DIOXIDE PRODUCTION

	Total glucose consumption ( $\mu\text{moles}$ )	Carbon-14 dioxide ( $\mu\text{moles}$ )
Control	2.33	0.13
+HGH	1.57	0.13
Control	2.33	0.13
+HGH	1.20	0.13
Control	2.70	0.11
+HGH	1.31	0.11

About 1.5 mo. of radioactive glucose- $^{14}\text{C}$  were added with carrier glucose to each flask (specific activity 118,000 c.p.m./ $\mu\text{mole}$ ). At the end of the 2 h incubation period radioactive carbon dioxide was collected by introducing 0.8 ml. of 4 normal sodium hydroxide into the centre well of a rubber stoppered flask and terminating the reaction by introducing 0.5 ml. of 4 normal sulphuric acid into the erythrocyte suspension with a hypodermic needle through the stopper. After the carbon dioxide had been collected it was precipitated as barium carbonate, plated to infinite thickness, dried, weighed, and counted in a windowless gas-flow counter.

cell lactic acid production<sup>1</sup> was found to parallel the fall in glucose consumption.

The increase in the intracellular concentrations of G-6-P and F-6-P that accompanies the inhibition of glucose uptake produced by HGH *in vitro* suggests an effect on glycolysis at or beyond the phosphofructokinase reaction.

Table 1 shows that the concentration of crude HGH (Wilhelmi H.8. 455.4) required to produce a 50 per cent inhibition of red cell glucose consumption was eight times that of the purified HGH preparation.

When crude growth hormone from other species was used at a final concentration of 128  $\mu\text{g/ml}$ , little or no effect on glucose consumption in human erythrocytes was found (Table 1). Porcine GH (NIH-GH P 365.4) had no effect, while the inhibitory effect of bovine GH (NIH-GH B10) averaged 16.2 per cent and that of monkey GH (Wilhelmi M 732.B) averaged 11.5 per cent.

Erythrocytes from two children with short stature secondary to congenital hypopituitarism showed the same response *in vitro* to crude HGH (128  $\mu\text{g/ml}$ ) as cells from normal subjects. Inhibitions of 52.6 and 45.8 per cent were recorded. These two children later responded to growth hormone administration with retention of nitrogen and acceleration of linear growth.

By contrast, an infant with multiple congenital anomalies and a chromosomal aberration who weighed only 1,750 g at 7 months, despite normal levels of growth hormone, failed to show the normal *in vitro* response to growth hormone. Glucose consumption was inhibited by only 14.1 per cent in this patient.

This *in vitro* model may be a simple system for evaluating the activity of growth hormone preparations in man.

This *in vitro* effect of HGH on glucose consumption in human erythrocytes may reflect a physiological control mechanism. The glucose consumption of human erythrocytes in the adult is said to average 24 g/day<sup>2</sup>. A mechanism to modulate glucose consumption in the fasting state when glucose is in short supply has not previously been recognized<sup>3</sup>.

We thank Dr A. E. Wilhelmi for providing the purified human growth hormone and the crude monkey growth hormone, the National Pituitary Agency, US National Institute of Arthritis and Mental Disease, for the supply of crude human growth hormone, and the Endocrine Study Section for supplying the bovine and porcine growth hormone. This research was supported in part by grants from the US Public Health Service.

## Uptake of Chylomicron Lipid by Rat Liver Parenchymal Cells *In vivo*

THERE are two theories about the uptake of chylomicron triglyceride by the liver. The widely held view that chylomicrons are removed intact from the circulation<sup>1-3</sup> has been challenged by Felts and Mayes<sup>4</sup>. They propose that the triglycerides are not taken up directly by the liver but are hydrolysed elsewhere by lipoprotein lipase, the resulting non-esterified fatty acids (NEFA) being taken up by the liver cells. *In vivo* evidence that intact chylomicrons are removed by the liver has been presented earlier<sup>5</sup> but was open to two objections<sup>6,7</sup>. First, heparin was used as an anticoagulant in the collection of the chylomicrons and sufficient could have remained after washing to stimulate lipoprotein lipase activity in the circulation. Second, studies on whole liver tissue may not give a true picture of events occurring in the parenchymal cells themselves, since trapping of chylomicrons in the tissue spaces does occur both *in vivo*<sup>7</sup> and in perfusion experiments<sup>8</sup>.

To overcome both objections, the following experiments were performed. Chylomicrons were obtained after administration of glycerol tri [1-<sup>14</sup>C] palmitate to rats in which thoracic duct cannulae had been established. The only heparin employed was a small amount in the saline filling the cannula when it was inserted. The first millilitre of lymph to emerge was discarded. The washed chylomicrons (0.75–2.05 mg of lipid) were injected into the exposed femoral vein of fed rats over a 30 sec period. One minute after injection was completed, the liver was perfused with ice-cold, calcium free Locke's solution containing 0.27 molar sodium citrate, and homogenized in Hanks solution. The homogenate was filtered through nylon mesh (60 $\mu$  pore size) and the filtrate centrifuged at 1,300*g* for 1 min. The sedimented parenchymal cells were washed and the total lipid extracted for determination of <sup>14</sup>C distribution<sup>9</sup>.

Most of the <sup>14</sup>C-palmitic acid associated with the hepatic parenchymal cells is in the triglyceride, with much smaller amounts present in the phospholipids (Table 1). Thus although studies of total quantity of lipid taken up by the liver may not be valid if based on measurements of the whole tissue, the distribution of chylomicron lipid in the parenchymal cells is very similar to that in the whole tissue<sup>3,10</sup>. When tritiated palmitic acid was injected as a complex with albumin, 57.8 per cent of the radioactivity was in the phospholipids and 27.8 per cent in the triglyceride. These measurements were made on the whole perfused liver, since the distribution of the isotope shows that there is no problem of contamination by trapped fatty acid. If chylomicron triglyceride had been hydrolysed to NEFA before uptake by the liver cells, the distribution of radioactivity should have been similar in the two experiments. As they are so different, they confirm earlier findings<sup>3,10</sup> and establish that under normal physiological conditions chylomicron triglycerides are directly removed from the circulation by the liver cells.

Further evidence which counts against lipoprotein lipase filling an important role in the uptake of chylomicron lipids is given by the finding that, after inhibition of this enzyme with protamine sulphate, the pattern of uptake and metabolism of chylomicron lipids in liver is essentially the same as that seen when no inhibitor is used (compare refs. 3 and 5).

Table 1. DISTRIBUTION OF <sup>14</sup>C IN RAT LIVER PARENCHYMAL CELL LIPIDS 1 MIN AFTER INJECTION OF CHYLOMICRONS LABELED WITH <sup>14</sup>C PALMITIC ACID

Lipid class	<sup>14</sup> C distribution* in	
	Original chylomicrons	Liver cells after chylomicron injections†
Triglycerides	93.1	73.1 ± 2.4
Phospholipids	6.8	19.2 ± 3.0
Cholesterol esters	0.4	1.2 ± 0.4
NEFA	1.1	6.2 ± 1.1

\* As percentage of total lipid <sup>14</sup>C.

† Mean of 5 expts. ± standard error.

The failure of Felts and Mayes<sup>4</sup> to detect significant uptake of chylomicron lipids by perfused rat liver in the absence of lipoprotein lipase is difficult to explain. Their conclusion, however, that NEFA are the principal form in which fatty acids actually traverse the liver cell membrane is in agreement with our earlier findings<sup>3</sup>.

We are indebted to Dr J. E. French, Sir William Dunn School of Pathology, University of Oxford, for instruction in the technique of thoracic duct cannulation. This work was supported by grants from the Science Research Council and the US Public Health Service.

## Freeze-drying and Protein Denaturation in Muscle Tissue; Losses in Protein Solubility

IN the course of a search for possible relationships between the freeze-drying procedure and the subsequent extractability of proteins from the freeze-dried tissue, it was found that freeze-drying of ox muscle does not necessarily reduce the extractability of the component proteins separable by Halander's procedure<sup>1</sup> which employs, in sequence, 0.03 molar phosphate buffer and 1.1 molar potassium iodide. These findings were, in part, a confirmation of the work of Cole and Smithies<sup>2</sup> and of Connell<sup>3</sup> and support the thesis that freeze-drying need not cause irreversible denaturation of the proteins present. Furthermore, our results explain the observations of those workers who, in experiments in which the effects of dehydration and of high temperature were combined, found that rapid freeze-drying lowers the extractability of proteins<sup>4</sup>. Thinking that the losses in extractability reported might be caused by the high temperature generally used to accelerate freeze-drying, we tried to separate the effects of freeze-drying from those of high temperature. We were thus able to show that heat applied during the course of freeze-drying to accelerate dehydration may induce insolubility in the portion already dried, while the part still to be dried remains undamaged.

Tissue samples were cut from the longissimus dorsi taken from beef carcasses, 2 to 4 days after death. Two freezing rates were employed: (1) slices of tissue 1 mm thick were immersed abruptly in well stirred isopentane maintained at -150° C; (2) a piece of tissue roughly 2.5 cm thick was allowed to freeze in the still air of a cold room at -10° C (these pieces were subsequently cut into cubes 1 cm on edge for freeze-drying).

Freeze-drying was carried out in an all-glass high vacuum apparatus<sup>5</sup> in which the specimen chamber could be (1) maintained at any desired temperature and (2) isolated from the condenser by closure of a wide-bore stopcock. In all cases we maintained the specimen chamber at -10° C with the aid of an automatically regulated external cooling bath, to the point where either (1) the specimen contained about 2 per cent residual moisture (on a dry weight basis) or (2) contained less than 0.2 per cent moisture, these arbitrary points of "completion" being measured by the method of increase of water vapour pressure to equilibrium (with the sample still at -10° C).

After some of the freeze-drying runs, the dried tissues were allowed to warm to room temperature, air was admitted to the apparatus, and the tissues were immedi-

ately submitted to the protein extraction procedure. After other freeze-drying runs, we retained the samples under vacuum in the specimen chamber, which was then warmed in an oil bath until the temperature of the tissues reached 80° C, where the batch was maintained for 24 hours. When the tissues were dehydrated to the 2 per cent moisture level, the specimen chamber was isolated from the condenser throughout the 24 h period at 80° C. When dehydration to better than 0.2 per cent was sought, we maintained the connexions from the specimen chamber to the condenser. A comparison of the effects of heat in the presence of 2 per cent water and in the almost complete absence of water was thus afforded.

Extraction of the dehydrated tissues was carried out by disintegration in 0.03 molar potassium phosphate buffer of pH 7.4 in a Waring blender, followed by exposure of the washed residue to 1.1 molar potassium iodide in 0.1 molar potassium phosphate of pH 7.4 (ref. 1). Suspended fats were removed by filtration of the 0.03 molar buffer extract on a large filter paper. Non-protein nitrogen and low-salt-soluble proteins (extracted together by the dilute buffer and separated with the aid of trichloroacetic acid), and fibrillar proteins (dissolved by the 1.1 molar potassium iodide in 0.1 molar buffer), were each determined by the biuret reaction. The insoluble residue was determined gravimetrically after washing and drying. The results are presented in Tables 1 and 2.

The tables show that there is no loss in extracted protein or any increase in the insoluble residue as a result of freeze-drying, provided that the specimen chamber is maintained at -10° C throughout drying and afterwards warmed only to room temperature. On the other hand, exposure of tissue, freeze-dried at -10° C, to 80° C for 24 h leads to losses in extractability of low-salt-soluble and of high-salt-soluble proteins of the order of 30 per cent and 65 per cent respectively. Thus the exposure to 80° C has affected the structural (high-salt-soluble) proteins much more than it has the sarcoplasmic (low-salt-soluble) proteins and the percentage reductions in extractability are to a first approximation independent of the rate at which the tissue was originally frozen and independent of the limits to which freeze-drying was subsequently carried.

In other experiments, the detailed results of which are not reported here, we found similarly that extractability is not reduced after freeze-drying in a specimen chamber maintained at room temperature where the tissue remains frozen due to the evaporative cooling involved. Further, extractability is not reduced by simple drying of tissue (to a 2 per cent moisture level) at temperatures between 2° C and 20° C in conditions controlled to prevent freezing by evaporative cooling. We observed that extractability is equally high in samples freeze-dried to 2.0 per cent and to 0.2 per cent residual moisture.

Irreversible reactions of a type leading to losses of solubility are thus not encountered as a result of freeze-drying itself. Such reactions are, however, induced to a smaller extent in the sarcoplasmic proteins and to a

greater extent in the structural proteins by exposure of the freeze-dried tissue to 80° C.

The mechanisms by which these insolubilities are induced are open to many interpretations. The sarcoplasmic protein fraction consists of many different molecular species, the distribution and stability of which in the freeze-dried tissue may vary widely. The structural proteins, on the other hand, are distributed according to an orderly arrangement and are composed of myosin, actin and tropomyosin in the ratios 54:21:15 or thereabouts\*. Since we have observed a reduction in solubility of structural proteins of about 65 per cent in each experiment involving exposure to 80° C, we make the tentative suggestion that the myosin molecules may be rendered insoluble while actin and tropomyosin retain their extractability. Furthermore, since this 65 per cent insolubility is achieved by 24 h at 80° C in the presence of comparatively little water—less than that required to complete a monolayer on the protein molecules present—it seems likely that the decreased solubility results from cross-linking reactions between side chains of adjacent undenatured protein (myosin) molecules rather than by a coprecipitation of unfolded peptide chains (that is, through a "true" denaturation). It is possible, however, that a combination of both mechanisms is involved in much the same way as that proposed by Connell<sup>2</sup> for the case of freeze-dried muscle tissues exposed to temperatures of 37° and 50° C for prolonged periods.

Further studies are envisaged in which it would seem necessary to follow separately the losses in solubility of actin and of myosin as a function of the time during which a piece of freeze-dried tissue is maintained at a given high temperature and a given relative humidity.

We thank Mr David Schroeder for assistance.

## Vitamin Distribution in Human Plasma Proteins

APART from vitamin B<sub>12</sub>, very little is known about the relation of vitamins and plasma proteins<sup>1-3</sup>. By coupling the availability of pure human blood fractions with sensitive, specific microbial and chemical vitamin assays, the amount of vitamin in various fractions of human plasma was determined. Such information is needed for charting transport mechanisms for the various vitamins or, conversely, assigning transport functions to the various blood proteins.

The human plasma fractions studied were:  $\alpha$ -globulin (Cohn fraction IV-1);  $\beta$ -globulin (Cohn fraction III);  $\gamma$ -globulin (Cohn fraction II); crystalline albumin (crystallized four times); and  $\beta$ -lipoprotein. These were all homogeneous fractions prepared by the classic Cohn procedure. All fractions met the standards of the Protein Foundation, Boston, for homogeneous protein purity. The nitrogen content of each fraction was determined by the Kjeldahl procedure<sup>4</sup>.

The plasma fractions for vitamin assay were prepared as follows: (a) Thiamine; 100 mg of the fraction was suspended in 25 ml. of a filtered solution of papain (500 mg papain in 100 ml. distilled water). The suspension was incubated for 3 days at 37° C. After incubation, 25 ml. of aconitic buffer, pH 4.5 (500 mg of *trans*-aconitic acid in 100 ml. of distilled water; pH adjusted to 4.5 with

potassium hydroxide), was added and the suspension autoclaved for 30 min. The supernatant was then assayed as for blood with *Ochromonas danica*<sup>1</sup>. (b) Pantothenic acid; 50 mg of the fraction was suspended in 50 ml. of diastase solution (200 mg 'Clarase' (Fisher Scientific Co., New York), dissolved in 100 ml. distilled water and filtered free of debris). The suspension was incubated for 3 days at 37° C. After incubation, it was autoclaved for 30 min and the supernatant assayed as for blood<sup>1</sup>. (c) Biotin; 50 mg of each fraction suspended in 50 ml. of diastase solution (200 mg 'Clarase' dissolved in 100 ml. of distilled water and filtered free of debris) was incubated for 3 days at 37° C; after incubation, the suspension was autoclaved for 30 min and the supernatant assayed as for blood<sup>1</sup>. (d) Vitamin B<sub>6</sub> and riboflavin; 250 mg of each fraction suspended in 5 ml. of pH 4.5 citrate-phosphate buffer were autoclaved for 15 min. After autoclaving, 20 ml. of diastase solution (80 mg 'Clarase' dissolved in 20 ml. of distilled water). The suspension was incubated for 3 days at 37° C, then autoclaved for 15 min; 25 ml. of distilled water was then added. The supernatant was assayed as for blood<sup>1</sup>. (e) Nicotinic acid; 50 mg of each fraction suspended in 100 ml. of filtered papain solution (1 g papain in 100 ml. of distilled water). The suspension was incubated for 3 days at 37° C, and then autoclaved for 30 min. The supernatant was assayed as for blood<sup>1</sup>. (f) Vitamin B<sub>12</sub>; 200 mg of each fraction was suspended in 10 ml. of *trans*-aconitic buffer at pH 4.5 to which 5 mg of sodium metabisulphite was added. The suspension was autoclaved for 30 min; 10 ml. of distilled water was added after autoclaving. The supernatant was assayed with *Ochromonas malhamensis* as for blood<sup>1</sup>. (g) Total folate activity; 100 mg of each fraction was diluted with 10 ml. of phosphate buffer at pH 6.1<sup>16</sup> to which 10 mg of papain and 10 mg of ascorbic acid were added. The suspension was incubated at 37° C overnight, then autoclaved for 10 min and the supernatant assayed for total folate activity, including N<sup>5</sup>-methyl tetrahydrofolate (N<sup>5</sup>-methyl THF), as for serum<sup>16</sup> with *Lactobacillus casei* (ATCC 7469); the total reduced-folate activity except for N<sup>5</sup>-methyl THF was assayed in a similar way using *Pedococcus cerevisiae* (ATCC 8081); *P. cerevisiae* does not respond to total N<sup>5</sup>-methyl THF<sup>16</sup>. The difference between total folate activity and total reduced folate activity is taken to be total oxidized folate activity, including N<sup>5</sup>-methyl THF as well. (h) Vitamin A,  $\beta$ -carotene, vitamin E, and ascorbic acid; 200 mg of each fraction was suspended or dissolved in 2 ml. of distilled water. Extraction and determination of vitamin A and  $\beta$ -carotene<sup>16</sup>, vitamin E<sup>11</sup>, and total ascorbate<sup>13</sup> were carried out as for serum.

The results in Table 1 show that the  $\alpha$ - and  $\beta$ -globulins together contain the bulk of the vitamins distributed on plasma proteins. Ascorbate, biotin, and vitamin B<sub>6</sub> are found mainly in the  $\alpha$ -globulin; thiamine, pantothenate, and reduced folates occur mainly in the  $\beta$ -globulin fraction.

Table 1. PERCENTAGE OF VITAMIN IN HUMAN PLASMA PROTEINS\*

	IV-1 $\alpha$ -Globu- lin	III $\beta$ -Globu- lin	II $\gamma$ -Globu- lin	Crystal- lized albumin	III $\beta$ -Lipo- protein

Pantothenic acid	19 (11.0)	46 (25.4)	8 (18)	30 (164)	2 (11)
Nicotinic acid	23 (110)	23 (110)	16 (80)	18 (91)	23 (110)
Biotin	43 (1.8)	19 (0.8)	3 (0.1)	24 (1.4)	3 (0.1)
B <sub>6</sub> activity	64 (5.1)	13 (1.0)	11 (0.8)	6 (0.5)	6 (0.5)
Riboflavin	26 (2.6)	27 (2.7)	19 (2.0)	10 (1.0)	18 (1.8)
B <sub>12</sub>	35 (1.7)	43 (2.1)	0	0	23 (1.1)
Total reduced- folate activity excluding N <sup>5</sup> - methyl THF	27 (90)	40 (132)	3 (8)	2 (7)	28 (92)
Total oxidized folate activity including N <sup>5</sup> - methyl THF	19 (63)	4 (12)	6 (19)	5 (15)	66 (218)
Ascorbic acid	42 (52)	11 (13)	26 (32)	21 (26)	0
$\beta$ -Carotene	0	0	0	100 (54)	0
Vitamin A	0	50 (9)	0	0	50 (9)
Vitamin E	0	0	0	0	100 (231)

\* Numbers in parentheses indicate actual value in ng/mg nitrogen; vitamin B<sub>12</sub> and folates are in pg/mg nitrogen.

Riboflavin and vitamin B<sub>12</sub> are almost equally distributed between the  $\alpha$ - and  $\beta$ -globulins. Most of the oxidized folates and all the vitamin E are concentrated in the  $\beta$ -lipoprotein fraction; vitamin A is equally distributed between  $\beta$ -lipoprotein and  $\beta$ -globulin, whereas nicotinic acid activity is fairly evenly distributed in all the fractions. Besides carrying much of the biotin and pantothenate, albumin is the only fraction in which  $\beta$ -carotene was found.

Until now most of the work on the vitamin distribution of human plasma proteins centred around vitamin B<sub>12</sub><sup>1-3</sup>. Such studies showed that the activity of vitamin B<sub>12</sub> was mainly in the  $\alpha$ - and  $\beta$ -globulins. Our results are similar (Table 1).

It is still not clear why plasma proteins bind vitamins. Presumably, the plasma fractions act as vitamin transporters to metabolic sites, or as temporary storage depots. Vitamin binding is altered in some disease states. This is seen in pernicious anaemia and leukaemia<sup>12,14</sup>, where the ratio of vitamin B<sub>12</sub> binding by  $\alpha_1$ ,  $\alpha_2$ ,  $\beta$ -globulins is changed. During liver disease or injury, the concentration of vitamins in hepatic tissue decreases<sup>15</sup>; on the other hand, the circulating concentration of vitamin B<sub>12</sub> during an acute hepatitis infection increases<sup>14</sup>. In the latter instance, it seems that the liver has temporarily lost its capacity to bind vitamin B<sub>12</sub>, leaving to plasma binders the conservation of the vitamin B<sub>12</sub> released from the liver.

In surveying here the distribution of particular vitamins among particular plasma fractions, using the same assay methods for all the fractions surveyed, the differences in the vitamin distribution (Table 1) between these fractions acquired more significance than the comparison of absolute values obtained by other methods in other laboratories. Although we found that differences in vitamin distribution among human plasma fractions do exist (Table 1) we can now only speculate about the reasons for them.

We thank Mr G. Mann, Nutritional Biochemicals Corp., Cleveland, Ohio, for assistance in obtaining the fractions for study. This investigation was supported by grants from the National Institutes of Health, US Public Health Service, and the US National Vitamin Foundation.

## MICROBIOLOGY

# Lack of Correlation between Production of Interferon and Protection of Temperature in Mice Infected with Sindbis Virus

Most authors believe that interferon is important in the defence against virus infection<sup>1,2</sup>, but other non-specific factors may also be involved, such as hyperthermia, the importance of which has often been pointed out<sup>3-5</sup>. Some authors think that there may be a relationship between the production of interferon and the variations of the body temperature, with hyperthermia causing an increase<sup>7</sup> and hypothermia a decrease<sup>8</sup> in interferon production.

We have pointed out before that the inhibition of the development of vaccinia virus in the brains of mice, kept at 35° C, is connected with the thermal sensitivity of the development of the viral strain and not with the interferon production<sup>6</sup>. Vaccinia virus did not induce interferon in any significant amount, and so we conducted the same experiments with Sindbis virus.

Inbred albino mice (of the I.C. strain from the Institut de Recherches Scientifiques sur le Cancer, Villejuif), weighing 15–20 g, were kept in two separate groups, one at room temperature 20° C ( $\pm 2^\circ$  C) and the other at 35° C. After 48 h all the mice were inoculated intracerebrally with 3,000 p.r.u. of Sindbis virus. The mice kept at 35° C had access to two feeding-bottles, one with tap water, the other with salt water at 1 part/1,000. The rectal temperature of the mice was measured daily with an electric thermometer ('Ellab Z8' Electrolaboratoriet, Copenhagen). The temperature of the mice kept at 20° C steadily decreased as infection developed, while the temperature of the mice kept at 35° C remained constant at 1.5° C above the initial temperature of the mice of the first group. Most of the mice kept at 20° C developed paralysis and died. In the other group nearly all the mice escaped paralysis and survived (Table 1).

Table 1. RECTAL TEMPERATURE AND MORTALITY AMONG MICE INOCULATED INTRACEREBRALLY WITH 3,000 P.R.U. OF SINDBIS VIRUS

One group of animals is kept at 20° C and the other at 35° C.		
	Rectal temperature* (°C)	Mortality† (per cent)
Environmental temperature (°C)	20 ( $\pm 2$ )	37.3
	35	38.7
		50/55 = 90.9
		4/48 = 8.3

\* Rectal temperature was measured 3 days after infection.

† Percentage of mortality was determined 20 days after infection.

We investigated the development of the virus and the yield of interferon in both groups of mice. Every other day five mice in each group were killed. Their brains were collected and ground with 25 ml. of phosphate buffer saline in a homogenizer at maximum speed for 1 min. Brain suspension (1 ml.) was stored at  $-20^\circ$  C for virus titration. The remaining 24 ml. was dialysed at 4° C for 48 h against hydrochloric acid/potassium chloride buffer (pH 2.0). The acidified samples were neutralized with 1/5 normal sodium hydroxide and were centrifuged at 17,000 r.p.m. for 30 min. Sindbis virus was plaque assayed in chick embryo tissue culture. Mouse interferon was assayed by a plaque inhibition technique in mice embryo fibroblasts or cultures of L cell, using Sindbis or vaccinia virus for challenging. Preparations for assays were diluted in Eagle's medium. Monolayers grown for 24 h in 60 mm plastic Petri dishes received 1.5 ml. of each dilution of interferon. After incubation at 37° C for 6 h the fluids were removed. The cell monolayers were washed with saline and challenged with 60–80 p.r.u. of virus. After adsorption for 1 h at room temperature, 5 ml. of Eagle's medium containing 10 per cent calf serum was used in conjunction with vaccinia virus. The cultures

inoculated with Sindbis virus were overlaid with 0.7 per cent agar in Eagle's medium. The cells were incubated at 37° C in 5 per cent carbon dioxide. After 48 h a solution of neutral red was added to each culture and the plaques were counted. The interferon titre was expressed as the reciprocal of the dilution necessary to give a 50 per cent depression of the control plaque count ( $PDD_{50}$ ). Both techniques were efficient, but the mouse embryo cells, challenged with Sindbis virus, proved the more sensitive.

Throughout three successive experiments, each with sixty mice, we noticed a very significant inhibition of virus development in the mice kept at 35° C. The greatest yield of virus at either temperature was reached on the fourth day after inoculation. At the higher temperature the production of virus never exceeded 16 per cent of the amount observed among the mice kept at the lower temperature.

The same data apply to the production of interferon. The amount of interferon induced in the brains of the animals kept at an ambient temperature of 20° C was 320–1,280  $PDD_{50}$  but it never exceeded 80 in those kept at 35° C. Fig. 1 shows the time course of the production of interferon and virus in one of the three experiments.

Fig. 1. Time course of interferon and virus production in the brains of mice inoculated intracerebrally with 3,000 p.r.u. of Sindbis virus and exposed to environmental temperatures of 20° and 35° C. (●), Virus (p.r.u./brain) of the mice kept at 20° C; (○), virus (p.r.u./brain) of the mice kept at 35° C. Black columns, interferon ( $PDD_{50}$ /brain) of the mice kept at 20° C; white columns, interferon ( $PDD_{50}$ /brain) of the mice kept at 35° C.

Thus we may assume that there is no relationship between the survival of the mice kept at 35° C and an increase in the production of interferon, particularly because the production of interferon is lower at that temperature. We can therefore conclude that interferon is not active in the defence of the body against infection during experimental hyperthermia in mice infected with Sindbis virus.

These findings lead us to assume that, as we pointed out for mice infected with vaccinia virus, an increase in body temperature has a definite effect on virus multiplication,

probably by checking a thermal-sensitive event in the development cycle.

### Action of Ethidium Bromide on Growth of Herpes Virus in Cell Cultures

ETHIDIUM bromide (EB) (2,7 di-amino-phenyl phenanthridine 10-ethyl bromhydrate) is an antimicrobial drug which, like proflavine (an acridine), forms reversible complexes with nucleic acids<sup>1,2</sup>. *In vitro*, it inhibits DNA-polymerase and, at a lesser rate, DNA-dependent RNA-polymerase<sup>3</sup>. In the same way, EB and related phenanthridine derivatives inhibit the synthesis of nucleic acids in bacteria<sup>4</sup> and Ehrlich ascites cells<sup>5</sup>; they are also trypanocidal<sup>6</sup>. Moreover, the photosensitization of arboviruses<sup>7</sup>, the inhibition of their development<sup>7</sup> and that of a *Pseudomonas pyocyanea* phage<sup>8</sup> by these compounds have been reported. Although the responses of several virus-infected systems to the action of acridines have been given in detail<sup>9,10</sup>, the comparable interactions with EB have not yet been so clearly described. The present paper details the action of EB on herpes virus and its growth in baboon kidney cells.

We studied first the direct action of EB at 37° C on herpes virus in the absence and presence of light. Rabbit kidney cells, cultured in casein hydrolysate medium with 5 per cent calf serum, were inoculated with herpes virus (strain IP 593055). 42 h after inoculation the infected cells were frozen and thawed in their medium and cell fragments were eliminated by centrifugation at 1,000g for 10 min. 1 ml. of the virus suspension was distributed into each of 13 flat 60 ml. flasks. 0.5 ml. culture medium

Fig. 1. Action at 37° C of EB on herpes virus in the presence and absence of light. ○—○ 1,000 µg EB/ml.; x—x, 1,000 µg EB/ml.; ▼—▼, 1,000 µg EB/ml. + light.

Fig. 2. Action of EB on kinetics of herpes virus growth. ○—○, Untreated controls; ●—●, 1,000 µg EB/ml. 2 h before virus inoculation; □—□, 1,000 µg EB/ml. from the second to the fourth hour after virus inoculation.

containing 3 mg EB/ml. was added to eight of the flasks, and half of these were wrapped in aluminium foil to keep out the light. The five remaining flasks received 0.5 ml. of medium with no EB. All flasks were then kept for various periods at 37° C, 15 cm from three cold white lamps with a total power of 100 W. The residual virulence of each sample was immediately determined on baboon kidney cells by inoculating ten-fold dilutions, each dilution being inoculated into five tubes. The cytopathogenic effect was read on the third day after inoculation, and titres calculated according to the method of Reed and Muench<sup>11</sup> and expressed as log<sub>10</sub> TCID<sub>50</sub>/ml. Fig. 1 shows that EB has both an inactivating and a photosensitizing activity with herpes virus.

Because of this direct effect, the infected cell system should be exposed to EB only during the eclipse phase in order to study the effect of EB on herpes virus growth. 60 ml. flasks containing baboon kidney cell cultures in Eagle's medium<sup>12</sup> with 10 per cent foal serum were distributed into three batches, two of which were inoculated with herpes virus, the multiplicity of infection being approximately 30. After incubation at 37° C for 1 h, the inoculum was removed and the cell layers washed five times with Hanks fluid. Non-absorbed virus was then neutralized for 1 h at 37° C with a hyperimmune rabbit serum, which was afterwards removed. After three washings, each culture was placed for 2 h at 37° C in contact with 2 ml. of a solution of 1 mg/ml. EB in an Eagle medium containing 5 per cent foal serum for the first batch of tubes and 2 ml. of medium for the second batch. The supernatants were removed, the cells washed five times and 5 ml. Eagle medium containing 5 per cent foal serum added to the cell cultures. The cultures were incubated at 37° C. Flasks containing the third batch were incubated with EB for 2 h before inoculation. At different times, two cultures of each batch were frozen and thawed three times, mixed, and titrated.

Fig. 2 shows that EB has little effect on the kinetics of viral growth when added 2 h before inoculation at the maximal concentration, which does not modify the cell

viability for 24 h. On the other hand, when EB is added from the second to the fourth hour after inoculation, there is a delay of 4 h before viral growth begins, although growth from then on is normal.

The photosensitivity of virus grown on cells treated with various stains has been reported for certain arboviruses<sup>8</sup> and for polio virus<sup>14</sup>. In our experiments baboon kidney cell cultures were inoculated with herpes virus, and half of them were then treated with EB from the second to the fourth hour following inoculation. All the cultures were collected 24 h after inoculation, and submitted to three cycles of freezing and thawing. Viral suspensions obtained after centrifugation were illuminated at 37° C for 2 and 4 h under the conditions described. The residual infectivity of the virus from treated cells was 1.6 per cent after 2 h and 0.1 per cent after 4 h of light treatment; it was 7.6 and 1.6 per cent for virus grown in the cells not treated with EB. This finding shows that the virions formed by cells treated with EB also have a certain photosensitivity.

The direct action of EB on normal herpes virus as well as the properties of virus grown in cells treated with EB may be attributed to binding of the stain on the viral genome, which could inhibit its expression or favour its degradation under the action of light. The combination of EB with cellular and viral DNA, causing inhibition of cell synthesis (at high concentrations of dye) and blocking the transcription and duplication of viral DNA, probably also accounts for the effect of EB during the virus eclipse phase. The temporary character of this inhibition is interesting in view of the known *in vitro* reversibility of the DNA-EB complex<sup>1</sup>.

We thank Dr Karl Habel and Dr Gérard Orth for helping us write this manuscript and for very fruitful discussion. We also thank Miss Marie-Louise Ryhiner for excellent technical assistance. This work was aided by the Institut National de la Santé et de la Recherche Médicale.

## Isolation of SV<sub>40</sub> Virus and Its Effect on Renal Function in African Green Monkeys

SV<sub>40</sub> virus is of considerable concern, because it has been shown to be present in a number of samples of inactivated polio virus and adenovirus vaccines produced before 1960, and it is capable of inducing both chromosomal changes and tumours in certain experimental systems. Since the isolation of SV<sub>40</sub> virus from naturally infected monkeys was reported by Sweet and Hilleman<sup>1</sup>, several

investigators have examined experimental infection in monkeys and man with this agent. It has been shown that infection can be produced in African green monkeys by several routes of inoculation<sup>2,3</sup>. Inoculation of human volunteers<sup>4-7</sup> has resulted in low grade infection including some evidence of transient chromosomal changes. Furthermore, administration of this virus to hamsters has resulted in the production of tumours<sup>8,9</sup>.

The experiments reported here were designed to investigate the effects of intravenous infection of the African green monkey with SV<sub>40</sub> virus and to investigate the chief sites of viral growth and the possible effects on renal function in this primate.

African green monkeys (*Cercopithecus aethiops tantalus*) were used. When these animals arrived, they were first quarantined for 3 weeks and then transferred to individual sterile cages. They were tuberculin tested and checked for other infections. The animals were pre-tested for the presence of antibodies to SV<sub>40</sub> virus before infection. Only animals free of antibodies were used. SV<sub>40</sub> virus adapted to African green monkey kidney culture was inoculated intravenously using 1 ml. of infected tissue culture fluid which contained 5.2 TCID<sub>50</sub> (log<sub>10</sub>) of virus (experimental animals) or 1 ml. of control infected tissue culture fluid (control animals). The animals were divided into three groups, and each group consisted of two experimental monkeys and one control. Group 1 animals were killed 2 days after inoculation; group 2 animals were killed 2 weeks after inoculation; and group 3 animals were killed 2 months after inoculation.

Blood and urine specimens were obtained at 2-5 day intervals for 4 weeks, and at weekly intervals for an additional 4 weeks. Kidneys (separated into medulla and cortex), lymph nodes, spleen, liver and lung from dead animals were tested for virus and examined for gross and microscopic pathological changes.

Virus infectivity titres and neutralization tests on all virus isolates from every tissue tested were determined in primary tissue culture cells of African green monkey kidney (AGMK) free of SV<sub>40</sub> virus. Inoculated AGMK tube cultures were incubated in the stationary phase at 37° C and examined microscopically from days 8 to 14 after inoculation for cytopathic effect. Appropriate controls were maintained in each test. Infectivity and neutralization 50 per cent end points were calculated by the method of Reed and Muench<sup>10</sup>.

Laboratory tests<sup>10</sup> to detect possible renal damage and other functional changes were conducted on all surviving animals at 2 or 5 day intervals for 4 weeks, and at weekly intervals for an additional 4 weeks. The tests utilizing the blood specimens included sedimentation rate, total serum protein, albumin/globulin ratio, blood urea nitrogen and cholesterol. Uncentrifuged urine specimens were tested for specific gravity, pH, albumin, sugar, acetone, red blood cells, white blood cells, and casts (also red and white cells and casts after centrifugation).

The concentrations of infectious virus recovered from organs of monkeys killed 2 days, 16 days and 60 days respectively after intravenous inoculation of SV<sub>40</sub> are shown in Table 1. The titres of virus in infected animals 2 days after infection were larger in the cortex of the kidney, the lymph node, spleen and lung. Sixteen days after infection concentrations of virus in these organs had increased by factors of 2-3 log<sub>10</sub> with the greatest increase in the kidney medulla (3.5 log increase). The concentration of virus in the lung, however, decreased ten-fold. These results suggest that virus multiplication is limited to the spleen and kidney in particular and the reticulo-endothelial system in general. Although virus was recovered from all organs tested 2 months after infection, the concentrations were less than ten infectious particles/ml. of 10 per cent suspension of tissue homogenate.

Fig. 1 shows the concentrations of SV<sub>40</sub> virus recovered from the urine and blood at different times from 2-60 days after infection. Viraemia was detectable within 2

Table 1. TITRES\* (IN TISSUE CULTURE) OF SV<sub>40</sub> VIRUS ISOLATED AT DIFFERENT TIMES FROM AFRICAN GREEN MONKEYS AFTER INTRAVENOUS INJECTION

Organs tested	Group: Days:	Days after infection		
		1	2	3
		2	16	60
Kidney medulla		5.4	8.9	+
Kidney cortex		6.4	7.4	+
Lymph node		6.9	8.4	+
Spleen		6.9	9.4	+
Liver		5.4	6.9	+
Lung		7.4	6.4	+

+, Virus recovered but titre less than 1 log<sub>10</sub>/ml.\* Titres expressed as TCID<sub>50</sub> (log<sub>10</sub>)/ml.

days after intravenous inoculation of virus, and within 7 days after infection most of the virus in the blood had disappeared; and at 12, 16, 24, 30 and 60 days after inoculation no virus was detected. The greatest titre of detectable virus in the blood was 2.2 (log<sub>10</sub>)/ml. In contrast, virus was not detected in the urine of inoculated monkeys until 7 days after inoculation; thereafter the virus titre increased until it reached a peak of 4.0 (log<sub>10</sub>) 16 days after infection. This rise was followed by a gradual loss until, 2 months after inoculation, no virus could be detected in the urine.

Microscopic examinations of unspun specimens of urine revealed small numbers of red cells (3-30) and casts in two of four infected animals on the eighth to the thirteenth day after inoculation. Blood from the same animals showed increase of blood urea nitrogen to levels of 52 to 55 (normal control 15 to 30) on the thirteenth day after inoculation, and also elevation of blood cells sedimentation rates of 13 to 33 mm/h (normal control 2 to 10 mm/h) during the 2 weeks following inoculation. All other tests on urine and blood mentioned above were of the same values as in control animals.

None of the animals injected with SV<sub>40</sub> virus showed any clinical sign of virus infection. The investigations carried out on the blood and urine specimens showed that two of four infected animals did have red cells and casts in their urine. Examination of blood revealed moderate elevations of blood urea and nitrogen sedimentation rates primarily during the second week after inoculation; these were transitory effects, however, and did not occur in the three control animals.

There is suggestive evidence that SV<sub>40</sub> virus produced abnormalities of kidney function associated with viruria during the investigation as evidenced by moderate elevations of blood urea nitrogen and red blood cell sedimentation rates. Although silent infections in man

with SV<sub>40</sub> virus inoculated into volunteers<sup>7,8</sup> have been reported, microscopic pathological reports of organs (biopsies or autopsies) have not been available.

The data presented have shown that a rapid multiplication of SV<sub>40</sub> virus occurred in the various organs tested. Only 10<sup>-2</sup> (log<sub>10</sub>) virus was injected, yet within 2 days this ordinarily slow growing virus had multiplied so that more than 100 times the amount injected was present in the lung and over eighty times the amount injected in the spleen and lymph node. All other organs tested contained as much or more virus than was injected. After 16 days the virus in the spleen and kidney medulla had multiplied about ten-thousand-fold. Virus concentration, especially in the kidney medulla, coincided with the detection of virus in the urine at concentrations greater than that found in the blood 2 days after inoculation.

The results reported here confirm some of the observations noted in African primates infected by different routes with SV<sub>40</sub> virus<sup>2,3</sup>. Similar findings in mumps and cytomegalovirus infections of man, in which viruria occurred in the absence of or in the presence of low viraemia, have been reported<sup>11</sup>. In the investigations reported here, virus multiplication occurred at greatest titres in the medulla of the kidney, the spleen and lymph nodes 16 days after inoculation, although viraemia was not apparent at this time.

We thank Frank West, James Pounds, Mrs Mary Wypych, Sara Panzarella and Gilda Donatelli for their help.

### Terminology of Bacterial Fimbriae, or Pilli, and their Types

THE nomenclature of the non-flagellar filamentous appendages of bacteria is in a confused state and the need for clarification is increased by a renewal of interest brought about by findings that suggest that some types of these structures may play a part in bacterial conjugation<sup>1-4</sup>. The appendages were first clearly described and distinguished from flagella and extracellular slime by

Houwink and van Iterson<sup>4</sup>, who called them "filaments", an unspecific term which was also used by Brinton *et al.*<sup>5</sup>. The distinctive name, "fimbriae", was proposed by Duguid *et al.*<sup>7</sup> in 1955 and has since been adopted by most authors publishing work on the subject in Britain and elsewhere.

In 1959 Brinton<sup>6</sup> introduced the term "pili" (Latin, hairs) as a synonym, and later<sup>8</sup> urged that it should replace "fimbriae". As chief reason for preferring "pili", he argued that "fimbriae" was "linguistically incorrect" because it is used in English as a collective plural word meaning a bordering fringe, not as an ordinary plural word meaning a number of distinct fibres. This objection is erroneous, and indeed the same kind of objection could be raised to "pilus", which in Latin is sometimes used to mean "the hair" collectively, and in English, as "pile", is generally used in the collective sense.

It is true that some dictionaries, including the *Oxford English Dictionary*<sup>10</sup>, define the English use of "fimbria", or "fimbriae", as a fringe, but others, particularly scientific dictionaries, show also the alternative use of these terms as meaning, respectively, one and several distinct fibres. Thus, the *British Medical Dictionary*<sup>11</sup> gives "fimbriae", "a thread or fringe", and the *Dictionary of Biological Terms*<sup>12</sup> gives: s.v. fimbria, "one of the delicate processes fringing the mouth of tube or duct, as of oviduct, or of siphon of molluscs". In any case, the derivation of a scientific term from a Latin word need not be limited by the current use of the word in English, but may validly be based on any meaning of the word in Latin usage. As stated by Duguid *et al.*<sup>7</sup>, the meanings of "fimbriae" in Latin include those of "threads" and "fibres". The *Oxford English Dictionary*<sup>10</sup> gives: "L. *fimbria* thread, fibre, fringe", and the Berlin *Thesaurus Linguae Latinae*<sup>13</sup> gives quotations from Latin authors that show by context that "fimbria" was sometimes used to mean a single thread or fibre and "fimbriae" to mean several threads or fibres. Thus, "fimbriae" is not incorrectly or inappropriately derived, and since it has temporal priority over, and wider currency than, "pili", it should be used in preference to the latter term. Neglect of priority in such questions of terminology is liable to encourage a burdensome proliferation of synonyms.

A further cause of confusion has now arisen in relation to the classification of the different types of fimbriae. Brinton<sup>6</sup> has published a classification of six types, types I-V and F; type F fimbriae are the scanty filaments evoked by the male fertility factor F and are thought to play a part in bacterial conjugation. Later, Duguid *et al.*<sup>14</sup>, in an article they submitted for publication before they had seen Brinton's article, proposed a classification of seven types (1-6, and F). Unfortunately, only types 1 and F are the same in both classifications. Brinton gives little information about the properties and occurrence of his types II-V. His type II, however, is patently inadmissible, because the only distinguishing information he gives about it is that the filaments are 48 Å in diameter and that they were described by Duguid *et al.*<sup>7</sup>. The latter authors did not describe any fimbriae that were 48 Å in diameter; they described only the fimbriae of *Escherichia coli* that are 75-100 Å in diameter and are designated type 1 in both classifications. It seems that it will be necessary for authors wishing to refer to fimbriae of types other than 1 and F to state which classification they are using. In any case, because of lack of detailed information about some of the types of fimbriae that have been described the present classifications must be regarded as provisional.

A term seems to be required to describe the group of fimbriae associated with bacterial transfer factors. "Type F" is not appropriate for this use because, although F was introduced as an abbreviation for "fertility", it has come to be used exclusively to denote the activities of the F factor, the specific transfer factor of *Escherichia coli* K12. The term "F fimbriae" could therefore perhaps be reserved for the fimbriae dependant on the presence of

F. Only the F and fl+ transfer factors have so far been shown to determine the production of fimbriae, but there is no reason to doubt that fl- transfer factors stimulate the production of functionally similar appendages, which may have different antigenic and phage-adsorption properties from those of the F and related fimbriae. It is suggested that the group of fimbriae associated with transfer factors, that is, F fimbriae and their analogues, should be described as "sex fimbriae". This description will distinguish them from the common types of fimbriae (types 1-6), which appear to be determined by chromosomal genes and not to be essentially associated with bacterial conjugation.

### Infection by *Hemileia vastatrix*

RAJENDREN<sup>1</sup> has recently published observations on the nuclear life cycle of *Hemileia vastatrix* in which he describes penetration of the leaf as occurring by means of a "bifid infection peg" produced from an appressorium, which he considers does not lie over a stoma. The two branches of the "peg" are shown as growing from the appressorium over the surface of the leaf to penetrate two separate stomata. It is surprising that Rajendren does not comment on the fact that this method of penetration is quite different from that given in the literature and which was first described by Marshall Ward<sup>2</sup>.

During my investigations of the biology of *H. vastatrix*<sup>3</sup>, using a cellulose acetate film stripping technique, I observed several hundred penetrations. The appressorium was almost invariably formed so as to lie over a stoma and an infection peg was produced on its lower surface and grew directly down into the stomatal aperture. This agrees with Ward's observations. I never saw a penetration of the type figured by Rajendren, which would therefore appear, at the least, to be very exceptional.

## CYTOLOGY

Stomatogenesis and Cell Division in *Euplotes* inhibited by Ultra-violet Microbeam Irradiation

SELECTIVE irradiation of a small part of a living cell with an ultra-violet microbeam has been used to investigate functions of cellular organelles. Functions of the kinetochore, centriole and spindle fibre have been investigated in grasshopper<sup>1</sup> and newt<sup>2-4</sup> cells in culture, as well as functions of the nucleolus in HeLa cells in culture<sup>5</sup>. In addition we have investigated radiation damage and recovery phenomena in a living cell by this technique<sup>6-8</sup>. This work, which involved selectively blocking stomatogenesis, was intended to show the close relationship between stomatogenesis and cell division.

For cell material we used *Euplotes eurystomus* Stock III, supplied by Dr M. Saito of the University of Yokohama. The cells were cultivated in wheat extract at 22° C with *Chilomonas paramecium* as bait. In the culture conditions, the generation time of the cells was 15.5–23 h. The variation is mainly the result of the number and/or the growing condition of *Chilomonas*; when the bait protozoa are growing more rapidly in the culture, the cells have a comparatively shorter generation time and vice versa. The response of the cells to the irradiation is also affected by their growing conditions. The experiments described here were carried out with two types of cells in a logarithmic phase (type A) and in a pre- and post-logarithmic phase (type B). The cells were fed with two types of the bait protozoa in a growing phase (type a) and in a stationary phase (type b) after the irradiation, and so four groups of cells were used in each experiment. For example, when type A cells were irradiated and recultured by feeding with the bait protozoa of type a, the cells were abbreviated as type Aa cells.

The apparatus employed for irradiation was of the Uretz type, constructed by Izutsu<sup>1</sup> in our laboratory, and the microbeam spot was 2  $\mu$  in diameter on the focal plate. Exposure was usually for 2–3 min, using a high-pressure mercury lamp (Toshiba 80 W). One cell was pipetted from the culture and was closed with a small amount of agar-agar paste between a quartz coverslip and a glass slide. After fixing the cell by removing excess medium and paste with filter paper, part of the cell

was irradiated, and the cell was recultured in a glass slide with a hole filled with culture medium containing *Chilomonas* to examine the progress of division. The period of observation after irradiation was 40–60 h, and the cells divided at least once in most cases. Morphological examination was made by haematoxylin-eosin staining, acetic carmine staining, and the Chatton-Lwoff silver impregnation method, as described by Corliss<sup>9</sup>.

From morphological findings of the stomatogenesis on the cell surface and the reorganization bands of the macronucleus, the mitotic cycle of the *Euplotes* cells can be divided into three stages. Stage 1 (about 30 per cent of the generation time) is a period showing no stomatogenesis and no DNA synthesis; stage 2 (about 55 per cent of the generation time) is a period of both phenomena; stage 3 (about 15 per cent of the generation time) is a period of cytokinesis. The stomatogenesis appears synchronously with the DNA synthesis.

In the late stage 1 of the type Ab, Ba or Bb cells, we irradiated for 2.5 min a region adjacent to the oral apparatus, where the oral anlage of the daughter cell appears in the early stage 2. This region was called the stomatogenic region (Figs. 1 and 2, *sr*). In this experiment, none of the twenty-two irradiated cells divided when watched for 41–65 h, and at least three of these cells died on the sixth day. Three of the eight cells irradiated for 2 min divided at least once in this period. On the other hand, when the Aa type cells were irradiated there for 2.5 min all the fourteen cells showed subsequent division in a period of 43–45 h. In the early part of stage 2, when oral formation had begun, the irradiation of the region failed to block the subsequent division in all of the twenty cells irradiated for 2.5 min and even when irradiation lasted 4–5 min.

The irradiated site on the cell surface was observed as a slightly dark portion corresponding to the irradiation spot in form and size with ordinary illumination through a reflecting objective lens. In some cells ciliary movement was weakened shortly after irradiation.

In the control experiment a portion opposite the stomatogenic region across the adoral zone of membranellae (AZM) (Fig. 2 (2)) was irradiated for 2.5 min in late stage 1 of the type Bb cells. All five cells irradiated for 2.5 min divided 40–47 h after irradiation. When one or two portions of the AZM were given this dose, five of the seven cells divided at 39–41 h and each of the remaining two cells divided at 64 h and 92 h. The waving movement of the membranellae was not affected by irradiation. All five cells irradiated at a peripheral part of the cell were able to divide about 40 h after irradiation.

Zeuthen and Williams<sup>10</sup> examined morphogenesis between divisions in heat-synchronized *Tetrahymena*, and indicated that heat shock induced synchronization by interfering with the assembly of oral apparatus from available precursor proteins. Whitson and Padilla<sup>11</sup> have examined effects of actinomycin D on the stomatogenesis and cell division in temperature-synchronized *Tetrahymena*, and concluded that this drug inhibited the former and secondarily the latter. They could not exclude, however, the possibility that actinomycin inhibition in the cell division involves other blocks as well. The results of our selective irradiation strongly suggest that the stomatogenesis is a trigger mechanism in the onset of division in *Euplotes*, and that, when oral formation has begun, its process becomes relatively resistant to ultra-violet irradiation. The resistance of the stomatogenic region in the rapid growing cells may be caused by the recovery phenomena of radiation damage.

### Changes in Surface Charge of HeLa Cells during the Cell Cycle

A METHOD of obtaining large numbers of fixed cells in metaphase arrested by colchicine, from a population of cells growing on a glass surface, by a method dependent on the attenuated adhesion of the cells to the surface has been described<sup>1</sup>. A modification of this method was suggested to obtain a viable population of synchronous cells. This was demonstrated<sup>2</sup> and a method for obtaining large numbers of HeLa cells of which 80 per cent to 95 per cent showed mitotic figures has been described<sup>3</sup>. The decrease in attachment of the mitotic cells was ascribed to a decrease in the area over which the adhesion occurred<sup>1</sup>. It is, however, possible that there is a change in the intrinsic strength of the cell-glass adhesions arising from an alteration in the physical properties of the surface of the cells which round up during mitosis. One of the most easily determined of these properties is the  $\xi$ -potential arising from the cell surface charge, and accordingly we have made determinations of the electrophoretic mobility of parasynchronous populations of HeLa cells at various stages in the cell cycle.

Parasynchronous populations of HeLa cells were prepared by the method of Robbins and Marcus<sup>4</sup>. The mitotic index of such preparations was generally about 60 per cent to 85 per cent and the degree of synchrony as defined by Engleberg<sup>5</sup> was about 50 per cent. Where the cells were maintained in suspension culture throughout the cell cycle, the cell number and the rate of DNA synthesis were also determined as described before<sup>6</sup>.

Determinations of electrophoretic mobility were made in a cylindrical cell apparatus essentially the same as that described by Bangham, Flemens, Heard and Seaman<sup>6</sup>.

Cells to be measured were washed three times in cold 0.146 molar sodium chloride buffered to pH 7.2 with 10 per cent v/v 0.1 molar phosphate buffer. The cells were suspended to a density of about  $2 \times 10^6$  cells/ml. and small quantities of about 0.2 ml. of this suspension were introduced into the field of view of the microscope with a fine polyethylene tube attached to a 1 ml. tuberculin syringe; the electrophoretic cell was already filled with phosphate buffered saline. It was thus possible to obtain reliable values for electrophoretic mobility using about  $4 \times 10^5$  cells. Determinations were usually made at 0°C in order to arrest metabolic changes. Some measurements were made at 25°C, but in any case appropriate corrections for viscosity were made and the results

are presented as equivalent 25°C mobilities. Measurements were made on asynchronous cells from suspension culture, on freshly collected mitotic cells and on asynchronous cells collected from monolayer culture using EDTA. In each determination observations were generally made on between sixteen and thirty cells of the population.

The electrophoretic mobility of HeLa cells cultured in asynchronous suspension was observed on a total of 214 cells to be  $-0.98 \pm 0.06 \mu\text{sec/v/cm}$  at 25°C in the medium defined above. With different preparations values of between  $-0.95$  and  $-1.03 \mu\text{sec/v/cm}$  were obtained. The values obtained for eight separate preparations of synchronous cells at the moment of preparation, that is, at the mitotic peak, are listed in Table 1. These populations clearly display a greater mobility than asynchronous cells.

Table 1. ELECTROPHORETIC MOBILITIES OF SYNCHRONOUS HELa CELLS DURING MITOSIS

Experiment No.	Electrophoretic mobility ( $\mu\text{sec/v/cm}$ ) corrected to 25°C	No. of cells at each determination
1	$-1.21 \pm 0.09$	27
2	$-1.30 \pm 0.15$	40
3	$-1.41 \pm 0.11$	30
4	$-1.14 \pm 0.16$	26
5	$-1.24 \pm 0.10$	30
6	$-1.27 \pm 0.09$	30
7	$-1.25 \pm 0.17$	30
8	$-1.29 \pm 0.10$	24

It is possible that this increase in electrophoretic mobility is a property of cells grown in monolayer as against cells grown in suspension, rather than that it is associated with the period of mitosis. In order to test this suggestion cells were collected from an asynchronous monolayer using EDTA medium<sup>7</sup> and their mobility was compared with that of a synchronous mitotic population treated for a similar period with the EDTA medium. The results of this experiment are contained in Table 2. We thought it desirable to use EDTA rather than trypsin to collect the asynchronous monolayer because it has been reported that trypsinization can alter the electrophoretic mobility of cells<sup>8</sup>. The above experiment demonstrates that treatment of cells with EDTA probably does not affect their electrophoretic mobility and, further, that the enhancement of net negative charge previously seen is associated with the mitotic state and not with the method of cell culture employed.

Table 2. ELECTROPHORETIC MOBILITIES OF SYNCHRONOUS AND ASYNCHRONOUS MONOLAYER GROWN HELa CELLS

Cell population	Mobility ( $\mu\text{sec/v/cm}$ )	No. of cells at each determination	Temperature
Asynchronous monolayer cells collected with EDTA	$-1.06 \pm 0.10$	20	25°C
Synchronous mitotic cells treated with EDTA	$-1.36 \pm 0.10$	16	25°C
Synchronous mitotic cells without EDTA treatment	$-1.39 \pm 0.09$	20	25°C

In a further experiment a synchronous population of cells was collected at 37°C and then allowed to grow on in suspension culture for 26 h. Samples were taken periodically and determinations made of their electrophoretic mobility. It was found that the mobility rapidly fell away, reaching after 60 min a value only just distinguishable from that of asynchronous populations. During the interphase period the value obtained was exactly the same as for asynchronous suspension culture cells, but during the next period of cell division, as indicated by the growth curve, a significant increase in mobility occurred, although the scatter of the observations was increased compared with the freshly prepared mitotic population. These results are contained in Fig. 1 where the standard deviations of the mobility measurements are indicated.

The results reported here confirm the expectation that cells in mitosis in monolayer culture which are readily detached from the substrate display altered surface pro-

perties. Mayhew and O'Grady<sup>9</sup> have described similar changes in tissue culture cells forced into parasynchronous growth by the method of double thymidine blocking. It should be emphasized that this is a transient property and is in no way similar to the generalized increase in surface charge displayed by cells of rapidly proliferating tissues which has been reported by other authors<sup>10,11</sup>. The observed increase in surface charge density is probably only associated with a small time interval during the cell cycle. This would account for the fact that cells with abnormally large mobilities are not generally seen in electrophoretic observations of populations of asynchronous cells when measurements are made on only about twenty individual cells. Furthermore, because the parasynchronous mitotic populations can be expected to contain a comparatively large percentage of cells, dependent on the degree of synchrony, not displaying the transient charge increase, a larger scatter in the individual cell mobilities would be expected. This is reflected in the standard deviations of the mobilities of mitotic populations which are in general about twice those found for asynchronous populations, which difference could easily arise if the mitotic population contained 10 per cent to 20 per cent of cells with the interphase mobility.

The origin of the extra charge remains unknown. Treatment with neuraminidase reduces the mobility of both asynchronous<sup>9</sup> and mitotic cells considerably, indicating that a substantial proportion of the surface charge derives from peripheral sialic residues. It seems unlikely, however, that the increase is simply the result of a surface concentration of charge-bearing macromolecules as the cells round up for mitosis, because all the cells when taken up in suspension for measurement adopted a spherical configuration, thus minimizing their surface area.

### Natural and Induced Changes in Chromosome Size and Mass in Meristems

PIERCE<sup>1</sup>, in 1937, claimed to have effected large changes in chromosome size in meristematic root tip cells of *Viola conspersa* after treating seedlings with different culture solutions. For example, he reports that in seedlings grown for 2 months in a culture solution with a large content of phosphate the chromosomes were 300 per cent larger by volume than in seedlings grown in a solution without phosphate. We think that his results provide the only direct evidence to show that changes in chromosome size may be induced by external environmental influences. The results pose two questions of particular interest. First, did the induced changes in chromosome volume reflect changes in chromosome mass or merely represent changes in the organization, for example, the coiling, of the chromosome material? Second, were the induced changes associated with quantitative changes in chromosomal DNA and possibly, therefore, in genetic information? This question is especially pertinent because variation in chromosome size between different individuals is, normally, positively correlated with changes in the quantity of nuclear DNA<sup>2,3</sup>. The following is a brief account of an experiment with seedlings of rye (*Secale cereale*,  $2n=14$ ). The experiment completely confirms Pierce's results in showing that changes in chromosome size may readily be induced. The experiment also provides answers to the above questions in relation to chromosome mass and chromosomal DNA. In addition the experiment brings to light a variation in chromosome size, independent of the inducing treatments, that seems to be associated with the "ageing" of the seedlings.

Rye seedlings, 3 days after germination, were transferred to one of three solutions of the kind used by Pierce, that is, a standard culture solution with "normal" phosphate content, a "high" phosphate solution and a culture solution without phosphate. Chromosome size was estimated and expressed as the total volume in each cell. The volume was calculated from estimates at metaphase of the total length of chromatids and of their average width. For the calculation the assumption was made that the chromatids are cylindrical in form. Chromosome volumes at intervals during the treatments appear in Fig. 1.

The results confirm in every essential respect the findings of Pierce. Chromosome size in root tip meristems increases with increasing concentration of phosphate in the culture medium in which the seedlings were grown. The increase is consistent throughout the experiment and at 3 weeks the chromosome volume is 50 per cent greater in the seedlings grown in a medium containing a large concentra-

Fig. 1. Electrophoretic mobility of synchronous HeLa cells throughout the cell cycle (—○—). Rate of DNA synthesis (—□—) and cell numbers (—△—) are shown for the same culture.

Fig. 1. Volumes of rye chromosomes at metaphase in root tip meristems of seedlings grown in three different culture solutions. Each point represents the mean volume of chromosomes in metaphases from three root tips in each of two plants. ●, High concentration of phosphate in medium; ○, normal concentration of phosphate; and ◐, no phosphate.

tion of phosphate as compared with those in the solution without phosphate.

Apart from the difference in chromosome size associated with the different culture treatments a particularly striking feature of the curves in Fig. 1 is the pattern of chromosome change in relation to the age of the seedlings. In all treatments the size of the chromosomes increases up to about 3 weeks and thereafter decreases to roughly the same level as in the newly germinated seedling. It is worth emphasizing that these changes apply to chromosomes in meristematic cells and thus are not comparable to the more familiar changes in nuclear phenotype which often accompany the differentiation of cells for specialized function. It is worth emphasizing also that "age" in this context applies to the seedlings and not to the roots. The roots examined were in every case young, new roots.

To find out whether the induced changes in chromosome size originate from change in content rather than in reorganization of the chromosome material, estimates were made, by interference microscopy, of the dry mass of isolated nuclei from root tips in each of the three solutions (Table 1). It is appreciated that while the dry mass of chromosomes at metaphase may not correspond exactly with that determined at interphase in the same tissue<sup>4</sup> there is every reason to suppose that the values are correlated<sup>3,5</sup>. Measurements of nuclear DNA, by Feulgen photometry, were also made and are given in the same table. The table shows that the induced variation in chromosome size is associated with variation in mass. There is no detectable change in the content of DNA.

While the precise chemical nature of the chromosome changes needs to be investigated further, the consistency in respect of the content of DNA would indicate that "accessory" non-permanent chromosome material is implicated in the induced chromosome variation. There is evidence that variation in such accessory material is often associated with the degree of synthetic activity of chromosomes<sup>6</sup>. Our observations in rye are consistent with this view. The volume and mass of the chromosomes were greatest in circumstances of rapid growth and, thus, of intense chromosome activity by way of nuclear and cell division

Table 1. MEAN CHROMOSOME VOLUME, NUCLEAR DNA CONTENT AND DRY MASS OF NUCLEI IN ROOT TIP MERISTEMS OF RYE SEEDLINGS GROWN FOR 3-4 WEEKS IN THREE CULTURE SOLUTIONS

Treatment	Chromosome volume (arbitrary units)	DNA content of 4C nuclei (arbitrary units)	Dry mass of nucleus $\times 10^{-11}$ g
40 p.p.m. of phosphate	128	23.65	9.4
18 p.p.m. of phosphate	105	23.92	6.4
No phosphate	85	23.43	5.3

DNA values were taken for ten nuclei in each of three plants, and dry mass values were taken for ten nuclei in each of five plants. The mass of the nucleolus is not included in these averages.

in the meristems; namely, in seedlings at 3 weeks—the period when relative growth rate is fastest—and in the fastest growing seedlings—those in the high phosphate solution.

## GENETICS

### Inheritance of Midpiece Length in Mouse Spermatozoa

INBRED strains of mice are known to differ in such aspects of spermatozoan morphology as the size and shape of the head and midpiece<sup>1-3</sup>. When inbred<sup>4</sup> or outbred<sup>5</sup> strains are crossed, clear patterns of inheritance of spermatozoan characteristics emerge. The first heritability estimates for characteristics of mammalian gametes were obtained by Napier<sup>6</sup> from son-sire regressions in the rabbit: for example,  $h^2 = 0.72 \pm 0.18$  for length of the spermatozoan head, and estimates of similar magnitude for its width and projected area. These investigations show in general<sup>7</sup> that genetic effects on the spermatozoan phenotype are paramount and environmental effects seem relatively unimportant.

It should therefore be possible to change spermatozoan characteristics by a genetic selection programme. This has now been tested in mice; the midpiece was chosen because its length can be measured with relative ease and accuracy. Duplicate nigrosin-eosin preparations of spermatozoa were made from each mouse by the method of Beatty and Sharma<sup>8</sup>. One of us (R. A. B.) coded the preparations of each generation and the other (D. M. W.) measured them in randomized order. Ten spermatozoa in each preparation were measured. The spermatozoa were viewed in a projection system consisting of a Gillett and Sibert "Conference" microscope (quartz-iodide light source) fitted with a  $\times 115$  objective, and a  $\times 5$  eyepiece instead of a prism head. On the ceiling an aluminized mirror was positioned to reflect the emergent light beam so that the principal ray fell perpendicular to an inclined drawing platform. Immersion oil was used both above and below the slides. The system gave a linear magnification of  $\times 6,136$ , the element of "empty magnification" being required so as to avoid the use of micro-methods in measuring the images. The length of the midpiece image, defined to include the "neck" (as before<sup>9</sup>), was represented on paper by a single pencil line drawn along the principal axis. The location of the distal end of the midpiece was facilitated by a colour contrast between the stained mainpiece and the unstained midpiece. Drawings were measured with a rotameter read to 1/32 in.

The general pattern of variation and repeatability of results was examined. Thirty-four son-sire pairs were drawn from two unselected generations of five related random-bred groups originating from "Q" strain (D. S. Falconer); nearly every sire was taken from a different litter. Age ranges were 96-114 days (sires) and 68-85 days (sons), but little or no effect of age was anticipated<sup>9</sup>.

Table 1. ANALYSES OF VARIANCE OF MIDPIECE LENGTH ( $\mu$ )

Item	d.f.	Sires		Sons	
		Mean square	Variance component (per cent)	Mean square	Variance component (per cent)
Groups	4	2.43	5	2.59	6
Males in groups	29	1.26*	30	1.35*	34
Preparations in males	34	0.233*	9	0.233*	9
Spermatozoa in preparations	612	0.0901	56	0.0837	51
			100 (0.162)		100 (0.164)

Total computed variance is shown in brackets. d.f., Degrees of freedom. \*  $P < 0.005$ .

From the analyses of variance in Table 1 it was concluded (a) that the principal components of variance are those for differences between spermatozoa within preparations (attributable, at least in part, to the limitations of optical resolution), and for the large and significant differences between males within groups; (b) the minor components are those involved in the differences between groups (non-significant) and in the significant but small differences between duplicate preparations; and (c) the general pattern of variation can be assessed with a large degree of repeatability between different generations, thus indicating reliability of technique and uniformity of material at each sampling level.

The mean midpiece length of each son was plotted against that of his sire (Fig. 1). The best estimate of heritability was considered to be one based on a joint son-sire regression within groups. A test showed that homogeneity of regression slopes between groups could be assumed. Only one sex was being measured, and so the joint regression coefficient was doubled to yield a heritability of  $h^2 = 0.97 \pm 0.36$  on 28 d.f. ( $0.025 > P > 0.01$ ). As in Napier's work with the rabbit, this value is in the higher range of heritabilities in general.

A selection programme was started with the object of realizing the rapid response predictable from the heritability estimate. A detailed account will appear elsewhere. A base population was constructed by crossing the five "Q" groups, and lines were selected for long and short midpiece, with a parallel control line. Spermatozoa were obtained from the vas deferens after killing the male; thus, litters had to be raised before the males were scored, and selection was made retrospectively on the litters. In each generation, between seventy-two and ninety-six males were scored, the litters of twenty-four of them being selected to give the next generation.

Fig. 1. Relation between mean midpiece length of sons and sires. The mean for each male is based on twenty spermatozoa, ten from each of two slides. The different symbols indicate the five groups.

Selection was practised within families in order to maintain a large effective population, and the matings between sibships followed a cyclical pattern designed to minimize inbreeding. The difference between the means of family means of the long and short lines (long minus short) in the successive selected generations has been  $+0.05$ ,  $+0.17$ ,  $+0.16$  and  $+0.28\mu$ , the trend of the control being intermediate between those of the long and short lines. The regression of these four figures on generation number, arranged to pass through the origin, is highly significant ( $0.005 > P > 0.001$ ). This response, agreeing so far with that predicted from  $h^2$  and the selection differential applied, appears to be the first reported for a purely gametic characteristic. Although small in comparison with the actual length of the midpiece of about  $22.7\mu$  as measured in nigrosin-eosin preparations, the response is large when compared with the variability of spermatozoa between males (for example, the figures of  $0.22$  and  $0.24\mu$  obtained by taking the square roots of the variance components for males within groups, calculable from the two analyses in Table 1). The experiment is being continued with an increased selection differential.

Two points of potential interest are being kept in mind as selection progresses. By increase in gene frequency, selection has been known to bring out in detectable (homozygous) form a recessive gene that was carried only by occasional heterozygotes in the original population, as in the "pygmy" gene of mice selected for small body size<sup>6</sup>. Thus there is the possibility that selection for gametic characteristics might amplify the very small existing list of specific genes known to affect the spermatozoan phenotype. A second interest is that selection for midpiece length is virtually a selection for the quantity or arrangement of mitochondria, and possible effects on the cellular constitution and other properties of the animals themselves are being sought.

### Heritability of the Plasma Transferrin Protein in Three Species of *Microtus*

ALTHOUGH variation in the electrophoretic mobility of the plasma transferrin protein has been demonstrated in a number of mammals<sup>1-13</sup>, not all investigations include work on the actual heritability of the protein. Cohen<sup>4</sup>, Shreffler<sup>7</sup> and Ashton and Braden<sup>14</sup> have all worked on the genetical control of this protein in the laboratory mouse (*Mus musculus*), but while the first two workers refer to the transferrin proteins, the latter two make reference to  $\beta$ -globulins. This occurs also in other instances in the literature. I therefore suggest that when an iron-binding method is used to identify this protein, as is the case in most of the work already carried out, perhaps the functional name, transferrin, would be more accurate than the general term,  $\beta$ -globulin, for it is possible that not all

the latter is being stained. This communication reports data gathered on the inheritance of the transferrin protein in the meadow vole (*Microtus pennsylvanicus*), the prairie vole (*M. ochrogaster*), and the beach vole (*M. breweri*).

Blood samples were collected from the tail tip in Fisher 'Scientific Red Tip' heparinized capillary tubes. Fisher 'Critocaps', haematocrit tube closures, were used when centrifuging the samples in the capillary tubes. The tubes were then broken just above the erythrocyte-plasma boundary and the plasma was gently blown out into the preformed slots in the starch gel. The starch gel system was run in essentially the same conditions as those described by Smithies<sup>15</sup> as modified by Poulik<sup>16</sup>. Transferrin protein bands were identified, using 'Canalco' series 800 Fe<sup>+++</sup> stain (Canalco, Rockville, Maryland).

The overall starch gel plasma patterns of the three species are very similar, the main difference being the gene frequencies of the transferrin alleles, which will be reported later when the investigation is completed. Because of their identical migration distances and appearances, the transferrins of all three species were named with the same system. This similarity of *Microtus pennsylvanicus* and *M. breweri* is not surprising, for the latter has diverged from the former perhaps within the past 5,000 yr<sup>17</sup>.

Six alleles, the most common being *TrfC* and *TrfE*, have been found in 2,000 *M. pennsylvanicus*; two alleles (*TrfC* and *TrfE*), the most common being *TrfE*, have been found in about 150 *M. breweri*; and two alleles (*TrfE* and *TrfF*), the most common being *TrfE*, have been found in thirty-four *M. ochrogaster*. I am following the suggestion of Cohen<sup>6</sup> in using *Trf* for "the mouse" transferrin locus because *Tf* used for the human transferrin locus might be confused with *tf*, the mouse tufted locus.

In order to see the differences in the gels clearly, the buffer front is allowed to run 15 cm. Fig. 1 shows relative mobilities of the separate alleles, each comprised of three zones. By varying the amount of starch per gel and thus the pore size of the gel, I conclude that the zones are caused by different net charges rather than by different molecular sizes, because less starch or an increase in the pore size only causes the zones to separate farther. This disagrees with the reasoning of Ashton and Braden<sup>14</sup>, who state that paper electrophoresis has no sieve action and thus the reason the zones seen in starch are not resolved in paper. I feel, however, that even with charge differences, the resolution of paper is poor enough that these zones, quite close to each other, could not be seen anyway.

Each main zone is preceded by two zones or bands each of the latter two decreasing in size. The smallest zone, closest to the anode, is sometimes difficult to see clearly. Combinations of two alleles (when they are homozygous the zones are proportionally larger) in each individual suggest the donation of one allele from each parent. Fig. 2 shows three of the transferrin phenotypes as seen

Fig. 1. Relative mobilities of the separate blood plasma transferrin protein alleles in *Microtus*.

Fig. 2. Three of the blood plasma transferrin phenotypes of *Microtus* as seen with starch gel electrophoresis: (top to bottom) *TrfC/TrfE*, *TrfE/TrfE*; *TrfA/TrfE*. O, Origin; T, transferrin; C, Hb contaminant; A, albumin.

in starch gel. The relative migration of haemoglobin is shown as a contaminant in the right-most sample.

\* Backcross, son to mother.

Table 1 gives the results of the laboratory crosses, all of which demonstrate normal non-sex-linked genetic inheritance. More than seventy-five pregnant females or females with nestlings were captured in the field and raised and tested in the laboratory. In all cases each offspring had at least one allele in common with its mother, as would be expected. These results give reasonable assurance that the transferrin protein is the product of codominant alleles in the three species of *Microtus* investigated.

## HAEMATOLOGY

### Haemocytes and the Measurement of Potassium in Insect Blood

It is normally tacitly assumed that potassium contained in haemocytes contributes insignificantly to whole blood measurements of this ion in insects<sup>1-3</sup>; van Asperen and van Esch<sup>4</sup>, however, explicitly state this to be the case.

Table 1. ESTIMATED CONTRIBUTION OF HAEMOCYTES TO WHOLE BLOOD ION LEVELS IN THE COCKROACH

Ion	No. of samples	Mean haemocyte count in 1,000's/ $\mu$ l.	Mean whole-blood concentration in mmoles/l.	Mean regression coefficient ( $\pm$ S.E.) of ion concentration for 10,000 cells/ $\mu$ l. in mmoles/l.
K <sup>+</sup>	46	31.7	8.8	+0.83 $\pm$ 0.09
Na <sup>+</sup>	44	32.1	148.6	-1.69 $\pm$ 0.52

Tobias<sup>5</sup> seems to be the only worker who has investigated the problem: he measured potassium in both whole blood and in serum, finding a 40 per cent difference. Some scepticism of this result has been expressed<sup>1,6</sup> but the problem has not been re-investigated.

Combined ion measurements and haemocyte counts were made on adult male *Periplaneta americana* of unknown age, but reared under identical environmental conditions. Duplicate haemolymph samples of about 5  $\mu$ l. were collected from each animal. The first sample, suitably diluted with 2 per cent di-sodium ethylenediamine tetra-acetate acid solution, was used for the haemocyte count; specimens were discarded if any clotting occurred. The second sample was mixed with 10 ml. of distilled water and used for the ion determinations (on a 'Unicam SP 900' flame photometer). The haemocyte counts and the ion concentrations are given in Table 1. The mean regression coefficient for potassium is +0.83 mmoles/l. for 10,000 cells/ $\mu$ l. of blood. That this positive correlation is not merely the result of blood dilution factors is indicated by the fact that the equivalent coefficient for sodium is negative, namely, -1.69.

It was not possible to confirm these results by more direct means. Because cockroach haemocytes release cytoplasmic threads within seconds of the animal being wounded, live blood will not separate properly in a centrifuge. It is therefore impossible to produce either uncontaminated serum or a measurable pellet of unbroken cells. A variety of anticoagulants and low temperatures were tried.

Treating the forty-six haemocyte counts on the basis that 10,000 cells/ $\mu$ l. represent 0.83 mmoles potassium/l. of blood indicates that a mean of 29 per cent (S.E.  $\pm$  2 per cent) of the whole blood potassium was contained within the haemocytes. In eleven of the specimens this figure exceeded 40 per cent and in four it exceeded 50 per cent. In the data provided by van Asperen and van Esch<sup>4</sup> for the same species the mean of 67,000 cells/ $\mu$ l. could have represented about 5.6 mmoles potassium/l. or some 70 per cent of their mean whole blood potassium concentration of 7.9 mmoles/l.

In cockroaches, at least, the haemocytes appear to contribute very significantly to the level of whole blood potassium. It seems reasonable to assume that in this intracellular state the ions play no immediate part in any concentration gradients across membranes separating tissues from blood. Several physiological estimations based on the assumption that whole blood potassium is entirely available to such systems may therefore have to be reconsidered. Haemocyte counts in other species<sup>7,8</sup> suggest that this situation may be common.

This investigation was supported by the US Air Force Office of Scientific Research through the European Office of Aerospace Research. I thank Dr Janet Harker, under whose supervision this work was performed, and Dr J. E. Treherne for advice.

## BIOLOGY

### Toxicity of Tobacco Smoke to the Spotted Alfalfa Aphid *Therioaphis maculata* (Buckton)

WE have been attempting to rear the spotted alfalfa aphid, biotype *ENT B* (ref. 1), on artificial diets after the manner of Auclair<sup>2</sup> and Dadd and Mittler<sup>3</sup>. Our initial unsuccessful attempts were conducted in an entomology laboratory. It was then observed that adults placed on potted alfalfa plants (*Medicago sativa* L.) in the laboratory did not produce viable nymphs, and that some of the adults crawled from the plants. Removal of the plants to a small greenhouse enabled normal nymph production after 2 to 3 h. We suspected two factors to explain this: the differences in the illumination or in the atmosphere between the laboratory and the greenhouse. In the laboratory, even with overhead fluorescent light, the aphids were phototropic to daylight. Because of the temperature and humidity fluctuations that occur normally in the field, we ruled out these variables from our consideration.

A group of adult aphids collected from field cages were randomized and placed on plants that had been kept in the laboratory or in the greenhouse for the preceding 18–24 h. A portion of each set was then transferred to the other locale. The adults lived and reproduced normally on the greenhouse plants in the greenhouse, whereas on those plants brought into the laboratory the adults maintained themselves, but the nymphs that were born immediately died and dropped from the plants. The results on the plants acclimatized to the laboratory were comparable. Those that were transferred to the greenhouse maintained the adults, and after a few hours the nymphs that were born were normal. The adults placed on plants kept in the laboratory did not produce nymphs and they usually crawled off the leaves on to the petioles and stems. This behaviour is also exhibited by aphids on resistant alfalfa plants.

Experiments were then conducted in a new, so far unoccupied building nearby. Potted alfalfa plants were placed in several of the rooms and infested with adult aphids. One room had daylight only, another daylight and fluorescent light, and the third daylight, fluorescent and incandescent light. In all cases, after a day, adult behaviour and nymph production were normal. A single cigarette was smoked in one of the rooms. The floor of the room measured 9  $\times$  12 ft. and the ceiling was 10 ft. high. Within 0.5 h the nymphs fell from the leaves and died. The smoke from three additional cigarettes caused the adults to fall from the leaves and die on the floor.

Plants were set up in ten unoccupied rooms and each was infested with ten adult aphids. The next day each plant had the original adults plus 40–60 first stage nymphs. In six of the rooms a single cigarette was smoked (different trade marks from different manufacturers), in the seventh a cigar was smoked 5 min, in the eighth a pipe was smoked the same length of time, in the ninth some paper was burned, and in the tenth fifteen wooden matches were ignited and burned. The nymphs fell from the plants and died in all rooms in which tobacco had been smoked and in no others. Subsequently, dry grass and dry alfalfa were burned in the tenth room, filling it with smoke, but with no effect on the nymphs or adults.

This shows that the spotted alfalfa aphid is extremely sensitive to tobacco smoke and that it is impossible to rear or study this insect in rooms or laboratories where smoking occurs. The nymphs, being killed in a room by the smoke from a single cigarette, are considerably more susceptible than the adults; however, the latter will die if a sufficiently high concentration of smoke is in the air, as during an afternoon coffee break or at tea-time. Also, when heavy smoking has occurred in a room and then is discontinued, nymphs born for several days after the smoking has stopped will die.

The principle in tobacco smoke toxic to the aphid is probably nicotine, an insecticide in use for almost 300 yr<sup>4</sup>. A bell jar experiment corroborated this. Ten adults and 200 nymphs on a plant under a bell jar were unaffected by two puffs of cigarette smoke that had been held in the lungs as long as possible. A single puff taken into the mouth and expelled into a second jar killed all the nymphs and all but one adult also died. Recent estimates place the nicotine content of an average cigarette at 10 mg, of which 6 mg is volatilized with the smoke<sup>5</sup>. The smoke exhaled from the lungs is almost devoid of the alkaloid<sup>6</sup>. This 6 mg would give a nicotine concentration of about 0.2 µg/l. in the air of the rooms used for the experiments. If nicotine is the toxic factor, 0.2 µg/l. is lethal to spotted alfalfa aphid nymphs and about 1 µg/l. to the adults. Previous work with the peach aphid (*Myzus persicae* Sulz.) on plants in a greenhouse showed 99 per cent adult mortality with 50 µg/l. in overnight tests<sup>6</sup>. Other work in fumigation chambers showed 6.5 µg/l. and 12.5 µg/l. to produce 100 per cent mortality with adult peach aphids and pea aphids (*Macrosiphon pisum* Harris), respectively, in 0.5 h tests<sup>7</sup>. These authors also showed that for a given nicotine concentration, mortality was higher at a lower humidity.

## Lingual Premetamorphic Papillae as Larval Taste Structures in Frogs

RISSER<sup>1</sup> was unable to demonstrate organs of taste in the mouth of the frog tadpole. More recently Helff and Mellicker<sup>2</sup> and Hammerman<sup>3-6</sup> have described lingual premetamorphic papillae on the tongue anlage of the frog. These investigators believe, on anatomical evidence, that the papillae serve as a taste sensor. This communication reports a behavioural study which was aimed at providing further evidence for a gustatory function of the lingual premetamorphic papillae.

First summer *Rana clamitans* and second summer *R. catesbeiana* larvae were tested in a black aquarium having inside dimensions of 16 cm length, 11.6 cm width and a height of 9.2 cm. A black painted partial barrier was placed across the centre of the long axis of the test aquarium. Conditioned tap water at 21.6°C was added to the testing tank to a height 1.7 cm above the top of the barrier. The stimulus substance was boiled leaf spinach, *Spinacia oleracea*, wrapped by a single layer of cheesecloth and lowered into the "test" compartment of the tank before the addition of a tadpole into the "start" compartment. The only source of light was a cool white fluorescent lamp at ceiling level 1.5 m from the test apparatus.

Each animal was tested for a period of 20 min. One minute was allowed to elapse before the timing was begun. A response was scored whenever a tadpole swam over the barrier and entered the "test" section of the aquarium;

a response was not recorded when the animal swam back over the barrier into the "start" compartment.

All tadpoles were anaesthetized in a 1 : 5,000 dilution of Sandoz MS-222 (tricaine methanesulphonate) in conditioned tap water. The olfactory tracts were transected by means of two transverse incisions—one at a level just posterior to the olfactory pits and a second 1 mm posterior to and parallel with the first. The sham operations consisted of two lateral incisions in an anterior-posterior direction, one on either side of the dorsal surface of the head. Premetamorphic papillae were removed by cutting them with irideotomy scissors at their area of attachment on the surface of the tongue anlage. Recovery of the tadpoles in conditioned tap water followed. Operated animals were not tested in the aquarium until at least 24 h after the completion of the operations. Verification of the various operations was made at the completion of the behavioural testing.

Table 1. MEAN CROSSING FREQUENCY OF EACH GROUP

Group	Mean crossing frequency per 20 min behavioural testing period
1 (120)*	8.28 ± 0.392†
2 (120)	2.98 ± 0.139
3 (120)	5.24 ± 0.217
4 (120)	2.57 ± 0.113
5 (50)	3.46 ± 0.203
6 (60)	4.83 ± 0.214
7 (50)	3.08 ± 0.208

The larvae to be tested were divided into seven groups: (1) Intact animals tested with no stimulus; (2) intact animals tested with spinach stimulus; (3) intact animals tested with cheesecloth control stimulus; (4) tadpoles with transected olfactory tracts tested with spinach stimulus; (5) sham operated animals tested with spinach stimulus; (6) tadpoles with both transected olfactory tracts and extirpated premetamorphic papillae tested with spinach stimulus; (7) sham operated animals with their premetamorphic papillae removed tested with spinach stimulus.

\* No. of animals comprising each group is given in parenthesis.

† Standard error of the mean.

The results obtained for each of the seven groups are listed in Table 1. The behaviour of the various groups reveals that when a stimulus, be it cheesecloth or spinach in cheesecloth, is placed in the "test" compartment of the aquarium, the tadpole will remain in this compartment longer than animals tested with no stimulus. When group 1 larvae are compared with all other groups of tadpoles they show a *P* value < 0.001 (Table 2). Thus it can be presumed that some stimulus is being received by the tadpole. No significant difference is noted between the behaviour of intact and olfactory tract sectioned larvae (groups 2 and 4). It can be assumed that the latter group of animals is utilizing a sense receptor other than the olfactory one.

Table 2. STATISTICAL COMPARISON OF BEHAVIOUR BY STUDENT'S *t*-TEST, SHOWING DERIVED VALUES OF *P*

Group compared with Group	<i>P</i>
1	2 < 0.001*
	3 < 0.001*
	4 < 0.001*
	5 < 0.001*
	6 < 0.001*
	7 < 0.001*
2	3 < 0.003*
	4 > 0.236
	5 > 0.268
	6 < 0.013*
	7 > 0.449
4	5 > 0.113
	6 < 0.002*
	7 > 0.259
6	3 > 0.334
	4 < 0.002*
	7 < 0.034*
7	4 > 0.252

\* Significant at the 95 per cent or higher level of confidence.

Comparison of the results of tadpoles in groups 2 and 6 reveals a significant difference. Group 6 larvae, with both the olfactory and postulated gustatory senses removed, are no longer capable of chemoreception. This would account for the increase in the average value shown by group 6 animals. One observes that these tadpoles begin to "wander" away from the spinach, thereby crossing the barrier more frequently. No significant difference is noted when comparing the behaviour of

group 6 with group 3, intact tested with cheesecloth larvae. It appears that tadpoles deprived of both the olfactory and gustatory senses (group 6) show the same behaviour as intact larvae tested with cheesecloth alone (group 3). Group 6 tadpoles differ significantly in their behaviour from larvae lacking only the olfactory sense (group 4). The increase in the average crossing frequency of group 4 tadpoles compared with that for group 6 is apparently due to the fact that the gustatory sensor of the latter group is absent.

The results obtained for group 7 tadpoles are significantly different from those with group 6. If the tadpole has the olfactory sense intact but lacks the premetamorphic papillae, then it probably utilizes whatever chemoreceptor it does have. There is no significant difference in the behaviour of larvae of groups 2 and 7. Because the animals of group 7 lack their premetamorphic papillae, the results indicate that these larvae are utilizing a chemoreceptor other than the gustatory one, namely, the olfactory sense. This may explain the closeness of the averages between the two groups.

No significant difference is noted when groups 4 and 7 are compared. Apparently, if the animal lacks a functional olfactory apparatus, it will utilize the remaining chemoreceptor, namely, the gustatory sensor, and vice versa. An animal with both senses functioning (group 2) probably uses both the olfactory and the taste receptors in combination. If one chemoreceptor of the animal is destroyed or functionally diminished, the tadpole will presumably utilize the remaining chemoreceptor.

A gustatory sensor thus appears to function in frog larvae. The absence of a differentiated taste epithelium indicates that some other structure acts as the gustatory sensor. Lingual premetamorphic papillae are the most likely candidates for this role.

### Axopodial Filaments of Heliozoa

PROTOZOA of the order Heliozoa are provided with numerous straight radiating processes known as axopods, which in certain genera (*Actinophrys*, *Actinosphaerium*) are known to be supported by axial filaments consisting of microtubules in elaborate array. In transverse section across an axopod these microtubules are seen to form two sheets spirally interwound (Fig. 1)<sup>1-3</sup>.

Further examination of the material prepared by Kitching and Craggs<sup>2</sup> and of additional material has revealed a system of links between the microtubules which form the axopodial filaments of *Actinosphaerium nucleoflum*. The links between tubules (Fig. 1) are of three kinds: tangential, radial and secondary. Tangential links are short and join adjacent tubules within either of the two spirally wound sheets of tubules; the separation between the tubules, centre to centre, is about 26 m $\mu$  in the sectioned material. The radial system of links is built around four primary tubules which form a parallelogram in transverse section. The tubules at two opposite corners each act as centres of a half circle containing six radii, each radius comprising a line of linked tubules. The whole system is divided into twelve sectors by these radii,

and within each sector the tubules of one of the bounding radii are linked with secondary lines of tubules. Thus each tubule of an axopodial filament is located within one of the two sheets and on a radius or secondary line. The spacing of the tubules, centre to centre, is about 47 m $\mu$  along the radii and 45 m $\mu$  along secondary lines, in the sectioned material.

The 30° angle between radial links at the centre suggests that the tubules have a fundamental twelve-fold radial symmetry, although this is never fully realized. Secondary links also conform. Markham rotations of a limited number of transverse sections of microtubules suggest that the wall of a microtubule comprises twelve sub-units—a figure close to that found in other material<sup>4-6</sup>. It is possible that sub-units could act as sites for linkage. Tangential links are thicker and shorter. They do not coincide with the hypothetical twelve-fold radial system, although they may be related to it. No radial or secondary links are found in their neighbourhood. The axopodial filaments are rooted either on the nucleus (*Actinophrys*) or in the perinuclear zone (*Actinosphaerium*) in a region rich in ribosomes, and it is to this region that we must look for an explanation of their origin and organization.

An axopodial filament of the configuration described can be increased in thickness by addition of microtubules to the outer ends of the two spiral sheets without any loss of regularity, but in the fixed and sectional filament of Fig. 1 the slight difference between radial and secondary links leads to increasing concavity within each sector towards the perimeter of the filament.

Although the axopodial filaments appear to act as supports for the axopods, we may speculate on a further possibility. Between six and a dozen independently moving longitudinal streams of protoplasm surround the filament. The sectors of secondary tubules might possibly drive these streams peristaltically. We might thus find justification for the elaborate structure of the filament and the differentiation of linkages. It is interesting that the undulating axostyle of pyrsonymphid flagellates is composed of parallel microtubules in six-fold radial linkage<sup>7</sup>.

Fig. 1. Schematic tracing of electron micrograph of axopodial filament.

In *Actinosphaerium* the twelve radial lines of microtubules would presumably isolate the active sectors from one another.

### Swarming of Hyperiid Amphipods

FOLLOWING a period of moderately strong westerly wind, on June 26, 1966, the beaches of Robin Hood's Bay, Filey, and Sandsend, Yorkshire (extending for about 40 km of coastline), were turned white by a covering of vast numbers of hyperiid amphipods.

A sample of these was found to consist of fifty-six large specimens, all but two being sexually mature or nearly mature, and more than a hundred small juvenile specimens. The large specimens were identified as *Parathemisto* (*Euthemisto*) *gaudichaudii* (Guerin), both the *compressa* and *bispinosa* forms<sup>1</sup> being present in about equal proportions. The small specimens could be identified with certainty only as *Parathemisto* sp., but considering that all of them were curled, as within the maternal oostegites, it was obvious that they had just been released.

Specimens of *Parathemisto* had occurred previously in small numbers in April and May 1966. In early June, mature specimens (containing young) were common in the surface plankton off Sandsend. Following the invasion of the shore, large numbers of small specimens of *Parathemisto* were taken in July in plankton hauls off Sandsend and only rarely were specimens taken later in the year. Thus swarming appears to be associated with the reproductive phase.

On June 17, that is, before the invasion, the stomachs of cod (*Gadus morrhua*) of 33–60 cm length trawled in 14 m of water, 1–2 km off Sandsend, were all found to be distended with specimens of *Parathemisto gaudichaudii* (identified by J. E. Kane). The cod were in large numbers and it seems likely that the amphipods had been swarming.

Swarms of *Parathemisto gaudichaudii* have been reported on other occasions; for example, off the Gulf of Maine<sup>2,3</sup>, off the French Atlantic coast<sup>4</sup> and in the Antarctic Ocean<sup>5,6</sup>. Where examined<sup>4,5</sup>, as in the present case, the composition of the swarms showed them to have been in a reproductive phase.

The coastline discussed faces north-east and the residual tidal current is south-east. Westerly winds activated by the Coriolis force might have intensified the south-easterly current and brought the swarming amphipods closer to the beaches. A similar invasion occurred in May 1913, also following a period of westerly wind<sup>7</sup>. Other invasions in February 1892, April 1907 and April 1908 followed periods of more directly onshore winds, north or north-east. Thus it is quite possible that the prevailing wind in each case could have contributed to the invasion of the shore by the swarming amphipods.

A sample collected from the beach at Redcar, Yorkshire, in April 1907 by T. H. Nelson was referred to as *Euthemisto compressa* by Ritchie<sup>7</sup>, and noted as *Euthemisto compressa* (Goës) var. *gracilipes* Norman (Reg. No. 1907–79, Royal Scottish Museum). According to modern usage this species is *Parathemisto* (*Euthemisto*) *gracilipes*<sup>8</sup>. On re-examination, this sample was found to consist of

110 specimens, all but five being sexually mature or nearly mature, many of the females carrying eggs or young. As in the 1966 invasion, the composition therefore suggested a reproduction phase although the species in the two invasions were different.

It appears that the neritic species<sup>8</sup>, *Parathemisto gracilipes*, is generally the most usual one in the southern North Sea<sup>9</sup>, although difficulty in nomenclature tends to confuse this<sup>10,11</sup>. Thus the presence of *P. gaudichaudii* might be considered unusual and, considering its normal oceanic existence<sup>1,8</sup>, indicative of an influx of water from the Atlantic Ocean. Similarly, swarms of the pteropod, *Limnacia lesueurii*, and of the radiolarian, *Phyllostaurus quadifolius*, normally in the Atlantic, occurred off the north-east coast of England in the late summer and early autumn of 1921<sup>12</sup>. These organisms were considered to have been carried around the north of Scotland. More frequently, successive swarms are brought only as far as the north of Scotland<sup>12</sup>. In 1965, for example, the euphausiid *Thysanoessa longicaudata*, which is normally oceanic, was found swarming in Lerwick Harbour in the Shetland Islands, where one would expect *T. inermis* or *T. rashi*<sup>13</sup>. Here, as with the amphipods, the swarm was in a reproductive state and is believed to have been influenced by local wind conditions.

The Sei whale in the Antarctic is reported to feed almost exclusively on *Parathemisto gaudichaudii*<sup>8</sup>, and the tunny (*Thunnus alalunga*) is known to feed on immense surface swarms of this species (as *Euthemisto compressa*) which occur beyond the continental shelf off the French Atlantic coast<sup>4</sup>. The cod off Langesnes, Iceland<sup>14</sup>, and off Bear Island<sup>15</sup>, has been reported to take *Parathemisto obliqua* (prob. = *P. abyssorum*) on some occasions as its predominant food. The feeding to gorging, as shown for the cod off the Yorkshire coast, however, is here reported for the first time.

This investigation was partially supported by a contract between the Scottish Marine Biological Association and the US Office of Naval Research.

### Apparent Photosynthesis and Respiration in Populations of *Lolium perenne* from Contrasting Climatic Regions

MEASUREMENTS of net assimilation rate by growth analysis techniques have shown significant differences between North European and Mediterranean populations of *Dactylis glomerata* in controlled environments at low and high temperatures<sup>1</sup>, and between a similar range of populations of *D. glomerata*, *Festuca arundinacea* and *Lolium perenne* in the winter, spring and autumn at Aberystwyth<sup>2</sup>. Greater net assimilation rates were found

for the North European populations in all these conditions. Variations in the rates of photosynthesis and respiration have also been reported for climatic races of *Solidago virgaurea*<sup>1</sup>, *Oxyria digyna*<sup>1</sup> and *Mimulus cardinalis*<sup>1</sup>.

Our experiments were designed to investigate the effect of temperature on the rates of apparent photosynthesis and respiration in two populations of *Lotium perenne* from contrasting climatic regions: one derived from local Danish material at Pajbjergfonden, Jutland, and the other from Boussarea, Algeria. The seedlings were grown in water culture at 20° C with a light energy of 0.093 cal cm<sup>-2</sup> min<sup>-1</sup> visible radiation, and 16 h duration, from warm white fluorescent tubes. When the seedlings had four leaves the carbon dioxide exchange of the whole plant was measured at 5°, 10°, 20° and 30° C with a null balance infra-red carbon dioxide analyser (Infra Red Developments, Ltd., Model SB/K2). An open circuit was used with clean air pumped at a rate of 2 l./min through a glass assimilation chamber containing the plants in water culture. The net exchange of carbon dioxide was measured by comparing the concentration of the gas in the air before and after passing through the assimilation chamber. The air temperature was regulated in a controlled environment room and the heating effect of the light, a 400 W high pressure mercury fluorescent lamp, was reduced by inserting a water bath below the lamp.

Values for dark respiration were obtained by measuring output of carbon dioxide in the dark at the beginning and the end of each range of light intensities; the results are shown in Fig. 1. There was marked temperature dependence of the rate of respiration, with higher rates in the Algerian than in the Danish population at 5° and 10° C and the reverse relation at 20° and 30° C.

A series of light energies from darkness to 0.233 cal cm<sup>-2</sup> min<sup>-1</sup> were used at each temperature to determine the relationship between apparent photosynthesis and light energy. Measurements were made for an ascending and a descending range of light energies. The results for a particular light energy varied little, therefore the mean of the two values was used. Five groups of plants were treated in this way at each temperature and it appeared that the Danish population reached light saturation at a lower light intensity than the Algerian population.

The following results were for a light energy which was below saturation in both populations.

A comparison of apparent photosynthesis between temperatures was made at 0.17 cal cm<sup>-2</sup> min<sup>-1</sup> visible radiation (Fig. 2); this was the same light energy as that used in growth analysis experiments with *Dactylis*<sup>1</sup>. There were greater values for net uptake of carbon dioxide in the Danish than in the Algerian population at 5° and 10° C but the differences were reversed at 30° C. The fastest rate was found at 10° C for the Danish and at 20° C for the Algerian population. The form of these curves for apparent photosynthesis against temperature at this light energy was very similar to the curves for net assimilation rate in cocksfoot<sup>1</sup>. Values for true photosynthesis derived from the measurements of apparent photosynthesis and dark respiration show the same pattern as the apparent

Fig. 1. The relationship between the rate of respiration and temperature for a Danish (solid line) and Algerian (broken line) population of *Lotium perenne*.

Fig. 2. The relationship between the rate of apparent photosynthesis and temperature for a Danish (solid line) and Algerian (broken line) population of *Lotium perenne* at a light energy of 0.17 cal cm<sup>-2</sup> min<sup>-1</sup> visible radiation.

photosynthesis but with smaller population differences at the temperature extremes.

It can therefore be argued that the lower rate of leaf expansion, and the accumulation of larger concentrations of fructosans in the North European, compared with the Mediterranean populations, at low temperatures in controlled environments<sup>1</sup>, and during the winter in Britain<sup>2,3</sup>, are the result of a different balance between the rates of photosynthesis and respiration. In the North European populations little energy is liberated through respiration and this may limit the rate of energy-requiring processes such as leaf expansion, while the rate of photosynthesis is fast and, because only a small proportion of the assimilates is used to produce new leaf tissue, the remainder are diverted to the base of the plant where they accumulate as fructosans. By comparison, the rate of respiration at 5° C is three times faster in the Mediterranean population, and a large proportion of the products of photosynthesis is used in the production of new leaf tissue; therefore low concentrations of fructosans accumulate in the base of these plants.

## AGRICULTURE

### *Eperythrozoon ovis* Infection and the Antiglobulin Test

DURING an investigation of *Eperythrozoon ovis* infection of sheep, attempts have been made to find laboratory aids to the normal practice of relying entirely on identification of the organism in blood smears. This method has limitations<sup>1</sup> in that: (a) parasites are detectable for relatively short periods and at a time when clinical symptoms are mild or absent; (b) careful handling of blood samples is necessary and not always possible under field

conditions; and (c) staining methods require exacting techniques and are inconsistent. One promising aid to diagnosis is a modification of the antiglobulin test of Coombs, Mourant and Race<sup>2</sup> described by Dacie<sup>3</sup>. References to the use of the Coombs test in naturally occurring diseases of animals are rare although the test has been used in certain experimentally induced anaemias.

Anti-sheep globulin serum is prepared in rabbits by Slavin's method<sup>4</sup>, inactivated by subjection to 56° C for 40 min and absorbed with washed red cells from the sheep whose serum was used to inject the rabbit. The test is routinely carried out in plastic haemagglutination trays at 37° C. At room or refrigerator temperatures in-saline agglutination may occur at certain stages of the parasitaemic cycle.

This method has shown that washed red cells from uninfected sheep and from sheep that are infected but not in an active phase of the disease show no agglutination at serum dilutions of 1:10. Cells from animals in which infection is or has recently been active, however, agglutinate in dilutions of up to 1:1,280—depending on the potency of the rabbit serum.

Limited observations, which require further investigation, suggest that the test generally remains negative during and after parasitaemic episodes after the first. In the early stages of *E. ovis* infection, therefore, the test should be valuable at least on a flock basis and preliminary observations suggest that this is so. Although the antiglobulin phenomenon in sheep may not be universally diagnostic of *E. ovis* infection, no other condition has been encountered in South Australia in which it occurs; in this state no blood parasites other than *E. ovis* are known to exist and the other known causes of anaemia are mineral deficiencies or excesses or helminths.

The use of sheep infected with *E. ovis* would also seem to offer opportunities for the investigation of the antiglobulin phenomenon itself.

## GENERAL

### A New Pseudo-tensor with Vanishing Divergence

MUCH embarrassment has been caused in the general theory of relativity by the fact that the conservation equation for the energy tensor  $T^{ab}$  reads  $T^{ab}_{;b} = 0$  (covariant differentiation) and not  $T^{ab}_{,b} = 0$  (ordinary differentiation). This led Einstein to construct a pseudo-tensor  $\tau^{ab}$  satisfying  $\tau^{ab}_{,b} = 0$  by adding to  $T^{ab}$  a suitably chosen pseudo-tensor formed from the metric tensor  $g_{ab}$  and its first derivatives. The purpose of this note is to offer a new way of reaching the desired equation  $\tau^{ab}_{,b} = 0$ .

As a consequence of the field equations  $G^{ab} = -\kappa T^{ab}$  and the identity  $G^{ab}_{;b} = 0$ , we have the conservation equation

$$T^{ab}_{;b} = T^{ab}_{,b} + K_a = 0 \quad (1)$$

where

$$K_a = \Gamma^c_{ab} T^{ab} + \Gamma^c_{ab} T^{ab} \quad (2)$$

Note that  $K_a$  is not a tensor, and the use of a subscript rather than a superscript is of no significance. It is convenient to use imaginary time ( $x^4 = it$ ), so that for the d'Alembertian operator  $\square$  we have  $\square f = f_{,aa}$ . The inverse d'Alembertian  $\square^{-1}$  is defined by the regarded potential

$$\square^{-1}f(x) = -\frac{1}{4\pi} \int \frac{f(x') d^3x'}{|\mathbf{x} - \mathbf{x}'|}, \quad x'^4 = x^4 - i|\mathbf{x} - \mathbf{x}'| \quad (3)$$

Define the pseudo-vector  $Q_a$  by

$$Q_a = \square^{-1}K_a \quad (4)$$

and the pseudo-tensor  $\varphi_{ab}$  by

$$\varphi_{ab} = Q_{a,b} + Q_{b,a} - \delta_{ab} Q_{c,c} \quad (5)$$

the summation convention for a repeated suffix operating here and throughout. Then

$$\varphi_{ab,b} = \square Q_a = K_a \quad (6)$$

If we now define the pseudo-tensor  $\tau^{ab}$  as

$$\tau^{ab} = T^{ab} + \varphi^{ab} \quad (7)$$

we have the required result

$$\tau^{ab}_{,b} = 0 \quad (8)$$

by virtue of equations (1) and (6). By adding  $\varphi_{ab}$  to  $T^{ab}$ , we have constructed a pseudo-tensor with vanishing divergence.

I refrain from attaching the words momentum and energy to this pseudo-tensor or to integrals formed from it, because I believe that we are barking up the wrong tree if we attach such important physical terms to mathematical constructs which lack the essential invariance property fundamental in general relativity. All that should be asserted is that equation (8) is a logical deduction from the accepted equation (1) and the mathematical definitions involved. The result may be found useful in dealing with solutions of the field equations by methods of successive approximations.

### Megayear and Gigayear

PROFESSOR RANKAMA<sup>1</sup> has rightly drawn attention to the prevailing disorder in geochronological time-units and the abbreviations used for them, and his advocacy of "megayear" and "gigayear" is worthy of support. But the current international abbreviation for "year", as adopted by the SUN Commission of the IUPAP and the British Standards Institution, is not "yr" but "a" (refs. 2 and 3) and the appropriate abbreviations for megayear and gigayear are thus Ma and Ga. The admittedly incongruous appearance (for English-speaking readers) of the first may perhaps explain why it has not yet been generally adopted.

## BOOK REVIEWS

### GUIDANCE FOR APOLLO

Space Navigation, Guidance and Control

Edited by J. E. Miller. (The Advisory Group for Aerospace Research and Development of the N. Atlantic Treaty Organization. AGARDograph No. 105.) Pp. x+373. (Maidenhead: Technivision, Ltd., 1966.) \$15.50.

In June 1965 a series of lectures on space vehicle control and guidance systems was given in Europe by members of the Massachusetts Institute of Technology, under the sponsorship of the Advisory Group for Aerospace Research and Development. This book is based on the material assembled for these lectures; the authors have all been actively engaged on the Apollo programme, and the problems of navigation, guidance and control are discussed with particular reference to this mission.

A manned lunar landing within the next few years may or may not be a laudable objective; but none can doubt the monumental nature of the task, the dimensions of which are vividly brought out in this account of the evolution of the Apollo guidance and control concepts as they now exist. The various phases of the operation—the initial injection into a near-Earth orbit, the Earth-Moon flight, the transfer to lunar orbit, the descent to the Moon's surface of the two-man "excursion module", its ascent and rendezvous with the command module which remains in lunar orbit, the return flight to Earth and re-entry through the atmosphere—present a very wide range of interacting navigational and control problems, all of which are thoroughly explored in a lucid and convincing manner.

The book follows the pattern of the lectures and is divided into seven parts. The fundamental principles of guidance and navigation are elucidated in the first part, which also discusses in some detail the characteristics of inertial instruments such as gyroscopes and accelerometers. The second part sets out the various tasks of the Apollo mission, in which the judgment and adaptability of the astronaut—in particular, his ability to recognize and evaluate patterns, and his decision-making capability in the face of the unexpected—are used to supplement, and sometimes to override, the automatic operation of the machine. Because, it is argued, men have to be carried to fulfil the mission, they should be active crew members rather than passengers.

The third part contains a simplified discussion of the numerous theoretical techniques which have been developed or proposed to ensure that the trajectories are in some sense optimal, while the following two parts of the book give a detailed account of the inertial and optical navigation sensors of the Apollo guidance and control system. On-board digital computers are treated in the sixth part, which includes a chapter on the Apollo guidance computer and a reminder that, in terms of data storage, "in to-day's guidance computer we are realizing an overall density thousands of times greater than in the computers of 15 years ago". The final part deals with the control of spacecraft attitude and of flight path during powered flight, coasting and atmospheric re-entry, again with reference to the Apollo mission.

The subject matter is of necessity drawn from a variety of disciplines in the engineering and scientific fields, and editor and authors are to be congratulated on the way in which they have managed to integrate these many topics into a readable and informative whole. The book

will be widely read, not only by guidance and control specialists, but also by those who wish to gain a deeper appreciation of the formidable yet fascinating problems involved in placing a man on the Moon with a valid return ticket to Earth.

E. G. C. BURR

### LUNAR POINT OF VIEW

Kepler's Somnium

The Dream, or Posthumous Work on Lunar Astronomy. Translated with a Commentary by Edward Rosen. Pp. xxiii+255. (Madison, Milwaukee, and London: The University of Wisconsin Press, 1967.) 88-75; 66s.

KEPLER'S *Dream* on lunar astronomy is a significant document in the development of cosmological thought. It has been overshadowed by Galileo's *Sidereal Messenger* and by Kepler's own work on planetary theory. This English translation, amounting to an impeccable critical edition, should help to redress the balance.

For Kepler himself, the imaginary voyage to the Moon was a life-long, but ill-fated voyage. The details of the journey thither came close to witchcraft, and the popular identification of the mother Fiolxhulde (the name chosen for its Icelandic barbarity) with Kepler's own mother, was an important factor in her subsequent prosecution for witchcraft. The piece itself was composed around 1609, but derived from speculations which had occupied him since 1593. These were an outline of astronomy as it would be developed by an observer on the Moon; their purpose was doubtless to be an indirect support for the Copernican theory. Some ideas on the voyage, and on biological and social aspects of lunar life, were already worked out when Kepler discovered the writing of Plutarch on the same topic. By 1609, he was well convinced of the Moon being an Earth-like planet, possessing mountains and inhabitants as well. The *Dream* itself has the unfortunate account of the voyage, an extended discussion of lunar astronomy, and a sketch of patterns of living there—all before Galileo turned his telescope to the Moon.

The "Notes" and "Geographical Appendix" (also with notes) were composed much later; and in the latter, detailed features of lunar topography are used as evidence for the presence of reason and of social organization on the moon. Galileo prudently abstained from such speculations.

This edition gives translations of the various texts (which were published together in 1634); there are copious notes and appendices on biographical and bibliographical topics. Professor Rosen's massive and meticulous scholarship will make this a standard source for many years to come. Historians of science will have their appetites whetted for closer studies of the influence of this work and of its reputation; and non-specialist readers would welcome an analysis of Kepler's lunar topography in the light of modern knowledge. But as a product of a sort of historical scholarship which is still not sufficiently developed in this field, this edition of the *Dream* deserves praise, study and emulation.

J. R. RAVEN

### GRAPHICALLY DESCRIBED

Connectivity in Graphs

By W. T. Tutte. (Mathematical Expositions, No. 15.) Pp. ix+145. (Toronto: University of Toronto Press; London: Oxford University Press, 1966.) 42s. net.

THE mathematical theory of graphs has become so extensive that an exposition in some depth of a part of the subject is welcome. Professor Tutte's book is such an exposition.

The twelve chapters in this volume (which is intended as the first of a set of three) are on topics which the author regards as related to connectivity. The choice of

such topics is to a large extent a personal one, and is naturally related to the research interests of the author. The treatment throughout is that of the pure mathematician. Definitions are precise, arguments are rigorous and there is no concern with applications. The opening sentences of the book define a graph in terms of an edge-set and a vertex-set which are not necessarily disjoint, and lead one to expect that diagrams of points and lines may not be used to represent graphs. The treatment is not, however, as severe as this and diagrams do illuminate the text in a substantial way.

The book is well written and, like most books on graph theory, demands no previous mathematical knowledge (even the term "group" is defined). The book is not altogether easy reading because the style is that of a research paper with close successions of definitions and precise proofs. There are several places, however, where the intuitive attractiveness of the research problems breaks through the formal rigorous treatment. This is particularly so in the chapter on girth and  $m$ -cages.

Research workers in graph theory as a part of pure mathematics will find much to interest them in Professor Tutte's individual treatment and will look forward to the two further volumes of the set. H. O. FOULKE

## ELECTRICITY AND FLUIDS

### An Introduction to Magnetohydrodynamics

By P. H. Roberts. Pp. vii+264. (London: Longmans, Green and Co., Ltd., 1967.) 60s.

This is a useful addition to the growing library of magnetohydrodynamic textbooks at the advanced undergraduate and postgraduate level. The bias of the book is mathematical, for its origins lie in a postgraduate course for mathematicians. Fortunately, some of the lecture room atmosphere comes across in the book, both in the preliminary comments, which open each chapter, and the way in which the topics are outlined and the central problems posed.

As the author admits, the scope of material he has discussed is strictly limited, and he has preferred to deal with a few problems in detail, rather than to give a general review of those subjects amenable to magneto-hydrodynamic treatment. Within these limits, however, a wide range is possible. The emphasis is geophysical and astrophysical—plasma physics enters only in theoretical exercises on hydromagnetic equilibrium and stability—and a chapter on compressible flow and magneto-gas-dynamics would have been welcome.

The essentials of the subject are given in the first two chapters and the rest of the book is devoted to their application to specific problems. These introductory chapters on the basic equations and electromagnetic induction are particularly good. Although the formulation is mathematical, the text is illuminated by those comments which physical scientists rarely expect from a mathematician. This measures the success of transposing the lecture course into book form.

The electrodynamic effect of the conducting fluid on the magnetic field through which it flows is considered in chapters on induction and dynamo theory. This latter chapter displays Professor Roberts's geophysical research interests.

The other aspect of the fluid magnetic field relationship, that is, the hydrodynamic effect of the magnetic stresses on the conducting fluid motion, follows in the section on hydromagnetic equilibrium, where several magnetic field configurations, familiar in plasma containment experiments, are reviewed.

Both sides of the interaction, the effect of the fluid motion on the field and of the field on the fluid, are then considered simultaneously in a discussion of Alfvén wave phenomena. The book is completed by chapters on

boundary layer theory, experiments on incompressible flow and on stability theory and its applications. Each chapter ends with a comprehensive set of problems.

The price is reasonable for a hard-back edition, but the book will reach many more students if it appears as a paperback. JOHN PAIN

## PLASMA RADIATION

### Radiation Processes in Plasmas

By George Bekefi. Edited by Sanborn C. Brown. (Wiley Series in Plasma Physics.) Pp. xiii+377. (London and New York: John Wiley and Sons, Ltd., 1966.) 125s.

Just over ten years ago the first book on plasma physics as a subject in its own right appeared; in a gradually swelling stream they have been pouring out ever since. Most of these books have been introductory; there have been surprisingly few monographs. One topic which has had scant coverage in any form is plasma radiation (except for spectral-line radiation which has been dealt with very fully in Griem's *Plasma Spectroscopy*). Professor Bekefi's book has now filled this gap.

*Radiation Processes in Plasmas* begins by recalling some results in the transport of radiation and generalizing classical radiation theory to anisotropic, non-thermal media before going on to discuss bremsstrahlung using a binary collision model; quantum modifications to the bremsstrahlung are summarized. The restriction to binary collisions is then relaxed and a more general point of view adopted by establishing the fluctuation-dissipation theorem and applying it to the fluctuations of the electromagnetic field. The dispersion relation for longitudinal waves in a thermal plasma and the damping suffered by these—the Landau damping—are compared with recent experimental results and the treatment of fluctuations ends with an extension of the fluctuation-dissipation theorem to plasmas not in thermal equilibrium—more often than not the case in practice.

The reader is now equipped to tackle the problem of radiation from plasmas more realistically. The considerations of bremsstrahlung introduced earlier may now be extended to bremsstrahlung from collective Coulomb interactions rather than from binary encounters alone. Some recent theoretical results on bremsstrahlung from plasmas which, though stable, contain a flux of supra-thermal electrons are included on the grounds that they provide a possible model (one of many!) for the type II and type III bursts of radiation from the Sun in its active phase. The bremsstrahlung comes, in this case, from the conversion of longitudinal plasma waves to radiation by scattering on the ions in the plasma; this coupling of longitudinal wave energy to the radiation field on a macroscopic scale (for example, through density gradients) is usually more important in laboratory plasmas and is treated in some detail.

The relaxation of the restriction that the plasma be free from magnetic fields adds enormously to the wealth of radiation phenomena. Again it is simpler to ignore collective effects and, to begin with, a single particle model is considered. Cyclotron radiation by non-relativistic electrons, by highly relativistic electrons (with applications to cosmic radio waves) and by "mildly" relativistic electrons (the regime of many fusion experiments) is evaluated before turning to the drastic changes in the emission spectra which appear once collective effects are taken into account.

The development then turns from the emission and absorption of radiation to the scattering of electromagnetic waves by plasma fluctuations. The spectrum of density fluctuations is derived for an isotropic, collisionless plasma and used to treat Thomson scattering and co-operative scattering both from thermal plasmas and those in which,

for one reason or another, the density fluctuations are enhanced.

The book ends with a quick tour through the maze of microinstabilities endemic in plasmas and a chapter on experimental methods.

In his preface the author remarks that the rapidly improving rapport between theory and experiment made this an opportune time to write a book on plasma radiation. On the other hand, one might have adopted the view that because this correlation between theory and experiment is going ahead so quickly the time was not quite ripe. One might back this up by pointing to significant new work not mentioned in the book, for example, results on the co-operative scattering of laser radiation by laboratory plasmas, the formation and heating of plasmas by powerful lasers and recent experiments which appear to establish the coupling between longitudinal plasma waves and the radiation field.

Workers in this branch of plasma physics will be glad that Professor Bekefi chose to write when he did. He has given a clear and balanced account of the subject (although the final chapter has the appearance of a peace-offering to the less theoretically minded). The references to the literature are very complete. The book is attractively produced and most of the mistakes spotted were obvious misprints or trivial omissions. The prospective reader should be familiar with classical electrodynamics and have some knowledge of plasma kinetic theory; he will find the going easier if he also knows something of waves and instabilities in plasmas.

Professor Bekefi has put workers in the field of plasma radiation considerably in his debt. T. J. M. BOXT

## MAKING ISOTOPES VISIBLE

### Techniques of Autoradiography

By Andrew W. Rogers. Pp. xi+335+71 illustrations. (Amsterdam, London and New York: Elsevier Publishing Company, 1967.) 120s.

THIS book is intended for biological research workers who wish to learn or extend the use of photographic emulsion in radioisotope localization and measurement.

The author's aim has been to give accounts of the major techniques with deliberate emphasis on the theoretical and practical aspects of handling nuclear emulsions, rather than the results obtained by autoradiographic methods. The volume comprises eighteen chapters and includes three chapters introducing radioisotopes and the photographic process. Further chapters cover the resolution and efficiency of autoradiographs, background, microscopy and microphotography, relative and absolute isotope measurements, the planning of experiments and histological technique.

Techniques which receive individual treatment include soluble compound methods, stripping film, liquid emulsion grain density and track autoradiography, electron microscope methods, and the treatment of macroscopic specimens.

With a few exceptions these subjects are covered well, sufficient data and references being given to allow the reader a clear understanding of the processes involved. Light microscope techniques for grain density and track methods are described in a comprehensive fashion that would allow the learner to obtain good results with the minimum delay. The data on track technique are especially welcome because these are not readily available elsewhere. The photomicrographic and automated counting techniques are also a valuable source of information, reflecting the author's considerable experience with these methods. Valuable advice is given on the choice of nuclear emulsions and their uses for various purposes, and on the inclusion of appropriate control experiments.

The chapters on soluble compound and macroscopic autoradiography are useful, although much of it has been published elsewhere. The chapter on electron microscope autoradiography is less satisfactory, for only one technique is given. Several other useful well tried techniques exist which might well have merited inclusion. The assessment of electron microscope results is poor compared with the treatment of light microscope preparations. The chief shortcomings of the book stem from the author's insistence on omitting literature concerned largely with applications to specific biological problems. The few examples cited are of a relatively unusual nature. Clearly a vast amount of selection would be required. Many points, however, would have been made clearer. More information would have been useful on preparation of specimens, particularly from the point of view of extraction of labelled compounds during embedding. The book is misleading on this point, especially in repeatedly recommending soluble compound techniques. Such techniques are of great importance. It must be made clear, however, that often useful autoradiographs are only obtained because selective extraction has occurred. The inclusion of some conventional applications together with their biochemical mechanisms would have clarified some of these points.

Dr Rogers has performed a useful service in making available in a single volume a great deal of information on autoradiograph technology. Despite the rather high price the book will find a place in the laboratories of all biologists who use photographic film to localize and measure radioisotopes. M. A. WILLIAMS

## THEORY OF ACCELERATORS

### Particle Accelerators

Edited by Rudolf Kollath. Translated by W. Summer. Pp. xiii+337. (London: Sir Isaac Pitman and Sons, Ltd., 1967.) 75s. net.

DR KOLLATH first published his book *Teilchenbeschleuniger* in 1954, and it was revised and enlarged with the help of other authors for the second edition brought out in 1962. This second edition has been translated by Mr Summer, who has added an appendix to record briefly some of the developments since 1962.

Although there have been no new fundamental ideas for particle accelerators discovered in the past ten years, technical advance in the realization of earlier ideas has been rapid and any book on the subject must be, to some extent, out of date almost before it is published. This book suffers particularly in this respect, for almost all the accelerators described have been running for a long time and some have actually been scrapped. General statements are made which may have been correct when the original book was written, but which progress has made no longer true. Also Dr Kollath falls into the bad habit of reporting (then) projected accelerators in the present tense, so that the reader would be forgiven for thinking that the Canberra ironless synchrotron had accelerated protons to 10 GeV whereas the project was abandoned some years ago. Therefore, one must judge this book on the success with which the principles behind the various types of accelerators are explained, rather than as a progress report.

Despite the fact that Dr Kollath wrote, or assisted in writing, most of the chapters, there is a considerable variation in the standard of previous knowledge expected of the reader. The publisher, in the end papers, states that "Mathematics is involved only where necessary to explain a point and even then is used with restraint" and "the book is highly recommended to degree students and all who have an interest in the study and application of particle accelerators such as medical men and engineers". Such restraint is not very noticeable in the longest

chapter in the book, on the theoretical treatment of accelerators with azimuthally variable magnetic fields, which includes a contribution to the theory of non-linear betatron oscillations. This would be an admirable paper on its own as an example of applied mathematics, but does not seem appropriate to the readership envisaged.

As an introduction to the theory of particle accelerators this book must be compared with Livingood's *Principles of Cyclic Particle Accelerators* and it loses in the comparison. Livingood gives a clearer, more coherent picture, and, despite the title, covers almost as much ground.

The translation is generally good, but some sentences which have been rather literally translated may have to be read twice before the meaning is clear, and some technical terms have suffered from being translated from English into German and then back again. A few errors have crept in, one leading to the statement that "the proton synchrotron supplies a powerful pulse of  $10^{-7}$  sec duration every five to ten seconds". M. C. CROWLEY-MILLING

## SEMICONDUCTOR PHYSICS

Proceedings of the International Conference on the Physics of Semiconductors, Kyoto, 1966

(*Journal of the Physical Society of Japan*. Vol. 21. Supplement, 1966.) Pp. xiii+780. (Minato-Ku, Tokyo: The Physical Society of Japan, 1966.) n.p.

THE eighth International Conference on the Physics of Semiconductors was held in September 1966, at Kyoto Kaikan, Kyoto, Japan, under the auspices of the International Union of Pure and Applied Physics, the Science Council of Japan and the Japanese Ministry of Education. The proceedings are published as a supplement to the *Journal of the Physical Society of Japan*, and contain 146 papers in all, including seven review and seventeen invited papers.

The programme of this conference had been very carefully chosen by the organizers so as to concentrate on new developments in the theoretical and experimental techniques used in the study of semiconductors and on the new phenomena revealed by these methods. There was very little routine reporting of experimental and theoretical work based on well established methods. This was the main reason for the unqualified success of the conference, in that it provided a demonstration of the fact that semiconductor physics is still a rapidly expanding subject with no apparent signs of saturation. The proceedings form an up-to-date picture of the state of the subject and serve to illustrate the increasing sophistication of semiconductor research and the ever-growing overlap with other branches of solid state physics.

The calculation of band structures has become something of a fine art these days, as is reflected in the papers contained in the session on band theory. The experimental determination of band structures is also becoming increasingly more sophisticated and accurate—a number of papers, either dealing specifically with this topic or having an indirect bearing on it, appear in the proceedings. The double session on optical properties contained a fine review of the theory of electromagnetic waves coupled to polarization fields by J. J. Hopfield. This review includes a brief survey of the usefulness of this theory, and it is interesting to note that its application to the problem of exciton spectra leads to very similar conclusions to those arrived at by Y. Toyozawa *et al.*, who treated the problem in terms of the competition between local and band features in the solid. This latter work was reported in the session on excitons.

The sessions on magneto-optics, impurity state, recombination, transport phenomena and quantum transport, while containing excellent reports of experimental and theoretical work, do not break any new ground apart from

showing how sensitive and complex the newer methods are. A typical example of this type of work is described in the paper by J. G. Mavroides on magneto-piezo-optical experiments.

The sessions on hot electrons, electron-phonon interactions and current instability are particularly interesting, not only because of the individual papers, but also because they show how the study of non-equilibrium phenomena has become more popular and fruitful. The past few years have seen great advances in the understanding of these effects—the Gunn effect, for example, has been explained only since the last conference in this series, as was pointed out by H. Y. Fan in his closing address. This part of the conference may well prove to be the most significant in that it contains the beginnings of a new trend in semiconductor research. The general impression given by these papers is that the next phase of development in the field of semiconductor physics will take the form of an investigation of those processes which occur when a solid is not in thermal equilibrium.

Another significant feature of this conference, which illustrates the rapid rate of expansion of the field, is the fact that whole sessions were devoted to both magnetic semiconductors and superconducting semiconductors. These are comparatively new topics which have only been studied for the past three or four years.

A number of new materials seem to have come into fashion. The layer-type semiconductor GaSe was the subject of two papers and tellurium attracted a certain amount of interest. These substances display interesting non-linear optical properties. Superconducting and normal  $\text{SrTiO}_3$  were also discussed. On the subject of material preparation, the general impression gained is that workers on a very wide range of substances are able to "tailor make" their materials to a very much greater degree than they could a few years ago. This state of affairs not only means that devices can be made to very close specifications, but also enables the experimenter to choose the exact conditions he requires for the study of the physical process in which he is interested.

The conference as a whole was a great success and the proceedings give an excellent detailed account of the individual papers including edited versions of the discussions which took place after each paper. The publishers are to be congratulated on making these proceedings available so promptly and on maintaining a very high standard of accuracy throughout. O. H. HUGHES

## RARE ELEMENTS IN ABUNDANCE

The Lovozero Alkali Massif

By K. A. Vlasov, M. Z. Kuz'menko and E. M. Es'kova. Translated by D. G. Fry and K. Syers. Edited by S. I. Tomkeieff and M. H. Battey. Pp. xvi+627. (Edinburgh and London: Oliver and Boyd, Ltd., 1966.) 252s.

LOVOZERO and the neighbouring intrusion of Khibiny, in the Kola peninsula, form one of the most extraordinary igneous complexes on Earth: they are unusually large masses of peralkaline syenite which contain abnormal amounts of rare elements, especially zirconium, niobium and rare earths. Any account of one of them could scarcely be uninteresting, but this large book, full of detailed information, does not match the fascination of its subject. A vast array of mineralogical and chemical data are collected together, and this is perhaps merit enough. But I should have liked a more penetrating description of the field and structural relations, the fabric and the texture, especially of the major rocks and minerals. The discovery at the outset that statements in the text are inconsistent with the illustrated sections (Fig. 5) must strain the credibility of the field descriptions in general. It is impossible to ascertain the form of the

whole massif, although it is implied to be tabular. When the authors come to the pegmatites, and the rare-element geochemistry, they are much more at home, and to this extent the book is mis-titled. Much of the description and the discussion throughout is ponderous and repetitive, although the reader searching for comparative data will find some good summaries and some excellent tables. The plates are of very mixed quality, and a number of figures have unsatisfactory explanations, scales or ornaments. The section on mineralogy is long and of variable consistency—petrologists will be disappointed by the section on rock-forming minerals; the pigeon-holing of some of the others, for example titanosilicates, tends to obscure their affinities. The final section of the book, on geochemistry and genesis, usefully gathers together many loose ends, but some of the averaging of chemical data is open to the criticism that the analyses, and the proportions of each, are not cited. The subsequent account of the mode of formation is not "a stimulating starting point for discussion". Nowhere is the suggested four-stage formation of rocks, as well as pegmatites, clearly substantiated. The remarkable mineral layering at Lovozero is ascribed to crystallization differentiation, but the mechanics of segregation are not postulated, and the phase-conditions governing the suggested sequences of crystallisation are not considered. A serious defect in this discussion is the scant consideration given to the neighbouring Khibiny massif; only the average chemistry is compared with that of Lovozero, and also, strangely, with Vishnevogorsk (only the reader familiar with Soviet geology would appreciate the latter incongruity—Vishnevogorsk is in the Urals province). In short, the factual part of this book is an invaluable, if unwieldy, addition to our knowledge of this uniquely important igneous complex.

D. K. BAILEY

## FEEDING FRUIT CROPS

### Nutrition of Fruit Crops

Tropical, Sub-tropical, Temperate. Edited by Norman Franklin Childers. Pp. xv + 888. (New Brunswick, N.J.: Horticultural Publications, Rutgers University, 1966.) n.p.

Most of the perennial plants that bear fruit crops of economic importance have much in common in their morphology and physiology, and certain general principles underlie their nutrition. Much empirical work has been carried out to determine responses to fertilizers and attempts have been made to provide bases for generalization about the application of results with a given crop to the various conditions in which the crop is grown. Little has been done, however, to integrate the research results to develop a generalized account of the nutrition of fruit plants. Although the present publication does not set out to do this, it performs a useful service in bringing together in one large book reviews on the nutrition of individual fruit crops.

Of the twenty-four chapters, nineteen are reviews, with lists of references, on the nutrition of apple; avocado and mango; banana; blueberry and cranberry; bush fruits; cacao; cherry; citrus; coconut; coffee; grape; olive; edible nuts; peach; pear; pineapple; plum, prune and apricot; strawberry; and tung. These reviews are mostly by American experts concerned with the respective crops. They show great variation in length and treatment; some give a critical assessment of their subject, while others provide a catalogue of experimental results sometimes in extensive tables quite out of place in this book. Many of the chapters retain the same form as in the original edition of 1954, the authors having been content merely to insert additional paragraphs, but some have been re-written. The accounts of the nutrition of banana, cacao, coconut, coffee, olive and pineapple are all new.

The book also includes chapters dealing with the use of leaf analysis as a guide to the nutrition of deciduous fruits and citrus respectively, an account of the use of chelated metals for supplying micronutrients to fruit crops, a chapter on experimentation with orchard trees, a comprehensive table of nutrient concentrations in fruit plant tissues in relation to the appearance of symptoms, and a ninety-eight page insert of monochrome photographs illustrating deficiency symptoms.

The contributions are all virtually independent. With few exceptions, there are not even any cross-references between the texts and the photographic section, so one has to use the subject index, fortunately a good one.

Defects occur, but they do not detract seriously from the value of this collection as a source of reference, on the whole well produced. Those concerned with the nutrition of one type of fruit crop should find it useful to consider what may be learned from the approach of others working with similar crops.

D. W. P. GREENHAM

## ECOLOGY LOOKS AHEAD

### Systems Analysis in Ecology

Edited by Kenneth E. F. Watt. Pp. xiii + 276. (New York: Academic Press, Inc.; London: Academic Press Inc. (London), Ltd., 1966.) \$11.50.

THIS is an excellent compendium of several recent and sophisticated research projects which have utilized electronic sampling devices followed by computer simulation or analysis.

Despite careful selection of the material, however, the reader is left with the impression that this, "the first book to present a detailed exposition of new electronic and computer procedures", is a little premature in its appearance. In several instances it is clear the authors themselves have indulged in some wishful thinking. The realism, for example, of both the direct study of bird navigation by means of orbital satellites, and direct links of computer with experimental situation, are both cases in point.

Many ecologists are not only aware of the complexity of the ecosystem and the desirability of team research but are also aware of the large gaps in our existing knowledge. This in turn leads to highly simplified simulation models. The wide range of the contents of this book does suggest a variety of ways in which the necessary data can be collected and handled by computer and it is in this respect a useful contribution.

It gives a firm jolt to those ecologists who are still prepared to amble along with merely notebook and pencil. Equally it promises those of us with an inadequate mathematical and electronic background some heavy going in the future.

K. A. KERSHAW

## NORTH AFRICAN BIRDS

### The Birds of North Africa

From the Canary Islands to the Red Sea. By R. D. Etchécopar and François Hüs. Translated by P. A. D. Hollom. Pp. xx + 612 + 24 plates. (Edinburgh and London: Oliver and Boyd, Ltd., 1967.) 168s. net.

As I remarked in the notice of the original edition of this book (*Nature*, 205, 9; 1965) it was appropriate that this valuable work of reference should be a product of French ornithology, which has been so notably active in the area. The material in the book is, however, also of great interest to British ornithologists and this English edition is welcome. The translator is one of the authors of the well known *Field Guide to the Birds of Britain and Europe* and himself a frequent visitor to North Africa. The present

book is itself more than a field guide, giving fuller information about behaviour and reproduction than is necessary merely for identification; the authors reasonably excuse its substantial bulk on the ground that travel in the desert anyhow necessitates a vehicle. The book gives a general account of all the bird species, resident and migratory, found in North Africa above about 21° N. latitude, including the Canary Islands. The translation very closely follows the original text, which the authors have not revised except to incorporate information from one recent source. They have, however, redrawn a dozen of the species distribution maps which are a feature of the work. The admirable illustrations by Paul Barruel, mostly in colour, are, of course, repeated.

LANDSBOROUGH THOMSON

## OUTSIDE THE NUCLEUS

### The Plastids

*Their Chemistry, Structure, Growth and Inheritance.* By John T. O. Kirk and Richard A. E. Tilney-Bassett. (A Series of Books in Biology.) Pp. xvi+608. (London and San Francisco: W. H. Freeman and Company, 1967.) 110s.

In recent years the investigations of the fine structure and function of plastids by electron microscopists and molecular biologists have confirmed what has long been apparent to those pursuing the more conventional approaches of cytogenetics and physiology, namely, that plastids have a dual role. They are both the seat of photosynthetic activity and the bearers of extra-chromosomal hereditary information with its associated protein synthetic activity. *The Plastids* is a timely and comprehensive account of both of these activities in which the old and the new are fairly balanced, carefully assessed and put into historical perspective.

The book is divided into four parts: the first is a short general description of the nature of plastids; the second is concerned with the inheritance and genetic autonomy of plastids illustrated by reference to the classical experiments on mutant and normal plastid differences in higher plants. An understanding of the nature of variegations and of the structure of chimeras is essential for a full appreciation of the significance of the breeding experiment and the observations on somatic segregation. The authors endeavour to provide this in the early chapters of the second part, although the combination of exhaustive detail, short sections and extensive cross-referencing makes heavy reading. Nevertheless, these are important chapters because the facts they contain provide the key to understanding how the separation of the chromosomal and extra-chromosomal contributions to the determination of the plastid phenotype has been achieved. But while we are spared none of the details of the origin and structure of variegations and chimeras, the authors' explicit desire "not to burden the reader" leads to a vague account of the mathematical properties of the sorting-out from cells containing a mixture of two kinds of plastids, which is devoid of the simplest statistical expressions, formulae and concepts. The binomial and hypergeometric distributions which are the theoretical basis for all models of sorting-out are not even mentioned.

The third part of the book gives the biochemical basis of plastid autonomy and plastid growth and accounts of the more recent evidence from electron microscopic and biochemical investigations. It contains a particularly good account of the genetical approach to the elucidation of the biosynthetic pathways which are involved in plastid development and in photosynthesis. Although every aspect of plastid structure and function in *Chlamydomonas reinhardtii* is referred to somewhere in the book, the evidence for post-meiotic reassortment and recombination

of extra-chromosomal determinants of the plastid phenotype in this species has been omitted, even though it has an important bearing on some of the speculative discussion in the third part.

The final part of the book is a short summary of the contents of the first three parts followed by speculations about the possible future developments in the field of plastid research. Similar summaries at the end of each chapter or part would have been invaluable in a book of this size and complexity. Unfortunately only three of the fifteen chapters and none of the parts have a concluding summary and many chapters end with a miscellany of material that could not find a place in their principal sub-sections. The book ends with three excellent indices for subjects, taxa and authors, respectively. These supplement the extensive references at the end of each chapter.

Taken as a whole, this book is an impressive work, beautifully illustrated and an invaluable source of reference. Its publication is a landmark in the acceptance of the extra-chromosomal contents of the cell as a partner of the chromosomal system in the heredity, growth and differentiation of green plants.

J. L. JINKS

## OBITUARIES

### Professor H. J. Muller

HERMANN J. MULLER, professor of zoology in the University of Indiana, Nobel laureate in 1946, died in Bloomington, Indiana, on April 5, 1967. He was born in New York City in 1890, and graduated from Columbia College in 1910. Here he had been influenced by the cytologist Edmund B. Wilson and the embryologist Thomas Hunt Morgan, who was beginning his studies of the genetics of the vinegar fly, *Drosophila melanogaster*. Muller began the experimental analysis of heredity at Columbia with the first group of graduate students to devote themselves to work with *Drosophila*, and in the same year, 1915, he obtained his Ph.D. with a dissertation on "The Mechanism of Crossing-over", and became co-author of the book which initiated the new era in genetics, *The Mechanism of Mendelian Heredity*, by T. H. Morgan, A. H. Sturtevant, Muller and C. B. Bridges. While at Columbia he made two discoveries which determined the course of his future work: the recognition of what became known as cross-over suppressors, later shown to be caused by inversion of gene order in part of a chromosome, and this in turn led to the discovery of the first balanced lethal system which provided the clue to the explanation of the recurrent "mutations" which de Vries had discovered in the evening primrose *Oenothera*.

The insights thus provided into the nature of the genetic system led Muller to invent ingenious breeding systems for the quantitative study of the mutation process. Much of this work was carried out at the University of Texas, where he was professor of zoology from 1920 to 1933. His paper on "The Problem of Gene Modification" provided the chief excitement at the Fifth International Congress of Genetics held at Berlin in September 1927. It brought convincing experimental proof that the mutation rate of genes of *Drosophila* could be increased 150-fold and more by treatment with X-rays. What set genetics on a new path was not merely the technical achievement of inducing mutations, both those with lethal and with visible phenotypic effects, in measurable quantitative rates. There was, in particular, the application of these methods to the problems clearly envisaged and pointed out by Muller of the analysis of the chemical and physical structure of the hereditary

material and of the process of evolution. Behind Muller's achievement lay the primary disclosure of the chromosome mechanism of heredity by E. B. Wilson (to whom Muller gave chief credit), T. H. Morgan and his students; after it came the detailed development of cytogenetics and the molecular basis of heredity. Muller participated actively in both the practical experimental and the theoretical development of genetics for more than fifty years, and left on it the indelible stamp of his ideas and vigorous personality.

He left Texas for Moscow in 1933 (he had taken the first cultures of *Drosophila* there in 1922), but abandoned the Soviet Union in 1937 to work first at the University of Edinburgh until 1940, then at Amherst College until taking up his professorship at Indiana in 1945.

Muller made important contributions to human genetics and to evolutionary theory through development of the classical theory of population structure (genetic load of mutations), and devoted increasing attention and enthusiasm to proposals for human betterment through control of human reproduction.

Throughout his work there runs a pattern of persistent use of mechanistic interpretations of biological phenomena. The success of these interpretations in genetics, as in physics and chemistry, led to an attitude of confidence which in Muller's case became overt optimism regarding the prospect of ultimate control by man over his own destiny.

L. C. DUNN

#### Professor F. A. Vening Meinesz

FELIX ANDRÉAS VENING MEINESZ, former professor of cartography and geodesy, and later also of geophysics, at the University of Utrecht from 1927 to 1957, and professor of geodesy at the Technological University, Delft, from 1939 to 1957, died in Amersfoort on August 10, 1966. He had been in hospital for six weeks after a fall at his home which caused a fractured hip; he was 79.

Vening Meinesz obtained his degree in civil engineering from the Technological University at Delft in 1910. Soon afterwards he was appointed engineer of the Netherlands Geodetic Commission and was commissioned to carry out pendulum observations in the Netherlands. This was a turning point which was to influence his whole career. On land he did pioneering work in this field, which he later repeated at sea. He was able to eliminate the disturbances caused by the irregular movements of the weak soil of the Netherlands by the so-called "two-pendulum method", and in 1915 he published the theory of his method in the thesis for his doctorate, entitled "Bijdrage tot de theorie der slingerwaarnemingen", after which he received his doctorate *cum laude*. In 1923 his "Observations de pendule dans les Pays-Bas" were published, describing the application of this method for fifty stations in the Netherlands. At this time Vening Meinesz was beginning to wonder whether this two-pendulum method could be applied with sufficient accuracy at sea as well. Tests made it clear that it would be difficult to fulfil the conditions of this method (equal amplitude and opposite phases of the pendulums) even in a submerged submarine. Vening Meinesz then realized that, independent of amplitude and phase, the difference in the angle of elongation of two isochronous pendulums, swinging in the same plane, was insensitive to horizontal accelerations, and that this angle could be regarded as the angle of elongation of a fictitious pendulum with the same period as the original pendulums. This method was worked out theoretically and instrumentally in his "Theory and Practice of Pendulum Observations at Sea" (1929), and it was used during the many submarine voyages which made him so well known. The results of all these voyages were published in the four volumes of *Gravity Expeditions at Sea*.

In the meantime Vening Meinesz published, in 1928, "A Formula Expressing the Deflection of the Plumbline in the Gravity Anomalies and some Formulae for the Gravity-field and the Gravity-potential Outside the Geoid", which became familiar to geodesists. His extensive gravimetric observations in the Indonesian Archipelago made it possible for this method to be applied for the first time at sea by Dr J. E. Baron de Vos van Steenwijk in his "Plumbline Deflections and Geoid in Eastern Indonesia as derived from Gravity".

Vening Meinesz continually emphasized the relationship between geodesy and geophysics. As a convinced supporter of isostasy, he tried to gather all possible information on the deviations from the state of equilibrium in the Earth. Combining this information with geological and seismological data, he always tried to make the geodesist better acquainted with the background to his science. He paid special attention, however, to trying to explain the reason for the irregular form of the Earth's crust. He considered that convection currents in the Earth's mantle were mainly responsible for the movements and consequent displacement of the continents. He was always able to express very difficult physical problems mathematically, as he had already done with the pendulum theory.

All those who knew Vening Meinesz were impressed not only by his great scientific knowledge, but also by his friendliness and hospitality, and his readiness to exchange ideas. He was awarded many Dutch and foreign decorations, honorary doctorates and the membership of many learned societies. One of his most important Dutch decorations was the "Eremedaille in Goud voor Voortvarendheid en Vernuft van de Huisorde van Oranje".

G. J. BRUINS

#### George Smith

GEORGE SMITH, who died on March 29, 1967, at the age of 71, started his career as a chemist. He graduated from Manchester University in 1916 and obtained his M.Sc. and A.I.C. in 1918. As chemist to a cotton manufacturing firm he met early the problem of mildew on cotton goods, and this led to the study of moulds, which was to become his chief work. In 1930 he joined Professor H. Reistrick at the London School of Hygiene and Tropical Medicine, where he remained till his retirement in 1961. Here he began with studies of the biochemistry of mould products, but became more and more involved in the taxonomy and care of the fungal cultures. During the Second World War he investigated the tropic proofing of military and naval equipment and thus became one of the first specialists in the field of bio-deterioration of materials. On retirement he continued his work on moulds at the Commonwealth Mycological Institute.

In 1939 he produced the first edition of *An Introduction to Industrial Mycology*. This book, with its magnificent photomicrographs, gathered together the information, much of it original, which hitherto scientists working in industry had found difficult to obtain. It is now generally used as an introduction to mycology for all those interested in moulds and moulding. Besides many short papers on the taxonomy, particularly of *Penicillium* and *Aspergillus* species, he produced monographs on the genera *Pasolomyces* and *Scopulariopsis*. All his work was undertaken with painstaking care and a meticulous attention to detail.

He enjoyed field work and was foray secretary of the British Mycological Society for some years, and was president of this society in 1946.

He was a quiet retiring man, kind and considerate, with diverse interests, covering all branches of science and philosophy. His favourite relaxation was music and he was an accomplished performer.

AGNES H. S. OMONS

## University News:

**Edinburgh**  
**DR NEIL CAMPBELL** has been appointed to a personal chair of chemistry.

**Liverpool**

The following appointments have been made: *Senior lecturer*, Dr D. V. Roberts (physiology); *Lecturers*, Dr H. A. Collin (botany); R. A. Latham (child health); Dr K. Lubkiewicz (child health); O. Thomas (civil engineering); P. Mars (electrical engineering and electronics); T. F. Varley (operative dental surgery).

## Announcements

The Medical Research Council has set up a Molecular Pharmacology Research Unit in the Department of Pharmacology, Cambridge, under the honorary directorship of Professor A. S. V. Burgen, to investigate the nature of the interactions between drugs and macromolecules and organized cellular structures. Further information can be obtained from Professor Burgen, Department of Pharmacology, The University, Downing Street, Cambridge.

## Meetings

**PHYSIOS**, Chemistry and Geochemistry of Asbestos Minerals, July 19-21, Somerville College, Oxford (Mr. W. P. Howard, Oxford Conference on Asbestos, 77-79 Fountain Street, Manchester 2).

**THE Mathematics of Solid State Physics**, July 23-26, University of Essex (the Secretary and Registrar, the Institute of Mathematics and its Applications, Maitland House, Warrior Square, Southend-on-Sea, Essex).

**NON-EQUILIBRIUM Processes in Astrophysics**, July 24-28, University of Manchester (Dr J. Hazlehurst, Astronomy Department, The University, Manchester 13).

**SOLUTION Properties of Natural Polymers**, July 25-27, Edinburgh (the General Secretary, the Chemical Society, Burlington House, London, W1).

**INTERNATIONAL Symposium of the International Society for Neurovegetative Research**, July 25-28, Royal Netherlands Academy of Sciences, Amsterdam (Professor J. Ariens Kappers, The Netherlands Central Institute for Brain Research, Ijdijsk 28, Amsterdam-O., The Netherlands).

**SEVENTH International Sedimentological Congress**, August 11-15, University of Reading and University of Edinburgh (Dr P. McL. D. Duff, Grant Institute of Geology, King's Building, West Mains Road, Edinburgh 9).

**FIBROUS Proteins**, August 14-18, Canberra (Symposium Secretary, Division of Protein Chemistry, CSIRO, 343 Royal Parade, Parkville N.2, Victoria).

**SPECTROSCOPY**, August 14-18, Brisbane (Dr D. James, University of Queensland, St. Lucia, Brisbane, Queensland).

**MEDICAL and Biological Engineering**, August 14-19, Stockholm (7th International Conference on Medical and Biological Engineering, Stockholm 60, Sweden).

**RADIOLOGICAL Health Problems**, August 17-20, McGill University (Dr D. Waldron-Edward, Honorary Secretary, Organizing Committee, Donner Building for Medical Research, McGill University, Montreal).

**ERRATUM**. In the communication "Nickel, Iron, and Manganese in the Metabolism of the Oat Plant" (*Nature*, 214, 828; 1967), the fifth sentence of the first paragraph should read: "The analysis of soil and minerals removed from both outcrops and subsoil, however, indicated that nickel alone was responsible for the condition of the crop. The level of cobalt in both soil and affected plants was little different from that in material from unaffected areas."

**ERRATUM**. In the article "Interaction of Basic Magma with Pelitic Materials", by C. D. Gribble and M. J. O'Hara (*Nature*, 214, 1198; 1967), the first sentence of the second column on page 1199 should read: "Residua consisting of an-mu-tr and an-mu, generated at  $t_1$ , and an-mu-coord, generated between  $t_1$  and  $t_2$ , would begin to melt with the appearance of liquid W, leaving residua consisting of an-mu-co, an-co and an-sp-co."

**ERRATUM**. In *Nature*, 214, 1182 (1967) the Fisheries Biochemical Unit at the University of Aberdeen was wrongly described as the Fisheries Biology Unit.

**ERRATUM**. The bibliography of *The Deer and the Tiger* (*Nature*, 214, 1372; 1967) should read: A Study of Wildlife in India. By George B. Schaller. Pp. 370+30 plates. (Chicago and London: The University of Chicago Press, 1967.) \$10; 72s. net.

**CORRECTION**. In Fig. 2 of the article "Three-dimensional Structure of Tosyl- $\alpha$ -chymotrypsin", by B. W. Matthews, P. B. Sigler, R. Henderson and D. M. Blow (*Nature*, 214, 652; 1967), the amino-acid at position 70 should read glu.

Mercury	R	Unfavourable for observation		21h 45m	+2.6	56	Gemini
Venus	S	22h 55m	21h 45m	20h 45m	-4.1	48	Leo
Mars	S	0h 05m	23h 15m	22h 30m	+0.2	93	Boötes
Jupiter	S	22h 00m	21h 10m	Unfavourable	-1.3	563	Cancer
Saturn	R	0h 00m	23h 00m	22h 00m	+0.9	860	Cetus

$D_p$  is the distance of planet from the Earth on the 15th of the month.

## OCULTATIONS OF STARS BRIGHTER THAN MAGNITUDE +6 AT GREENWICH

Star	R/D	Time	Mag.
76 Vir	D	14d 21h 31-0m	+5.4
$\sigma$ Sco	R	17d 22h 14-0m	+3.1
43 Oph	D	18d 22h 06-3m	+5.4

(D, disappearance; R, reappearance)

## OTHER PHENOMENA

- 3d 07h, Mars 1.4° N. of Spica.
- 8d 05h, Venus 0.3° S. of Regulus.
- 24d 10h, Venus at greatest brilliancy.
- 27d 14h, Saturn occulted by the Moon, visible N.E. Asia, N.W. America.

## FORTHCOMING EVENTS

(Meetings marked with an asterisk are open to the public)

Wednesday, July 5—Thursday, July 6

MUFFIELD COLLEGE OF TECHNOLOGY (at Queensway, Muffield, Middlesbrough)—Symposium on "Mass Spectrometry".

Monday, July 10—Thursday, July 13

INSTITUTE OF ELECTRONICS AND RADIO ENGINEERS; INSTITUTE OF PRODUCTION ENGINEERS; and the INSTITUTE OF ELECTRICAL ENGINEERS, ELECTRONICS DIVISION (at the University, Nottingham)—Joint Conference on "The Integration of Design and Production in the Electronics Industry".

## APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

LECTURER (preferably with a particular interest in mechanical vibration) in the MECHANICAL AND MECHANICAL GROUP of the DEPARTMENT OF MECHANICAL ENGINEERING, to contribute to the teaching and research work of the Department in the field of dynamics—The Secretary to the University Court, The University, Glasgow (July 7).

ASSISTANT LECTURER in the DEPARTMENT OF PHYSICS—The Registrar, The University, Leicester (July 8).

ASSISTANT LECTURER or LECTURER (with an interest in experimental taxonomy, physiological ecology or plant physiology) in the SCHOOL OF BIOLOGICAL SCIENCES—The Registrar, University of East Anglia, Norwich Hall, Norwich, NR8 89C (July 8).

ASSISTANT LIBRARIAN (graduate)—The Secretary, Queen's College, Dundee, Scotland (July 8).

JUNIOR LECTURER in PHYSICS—The Secretary, Trinity College (University of Dublin), Dublin 2, Republic of Ireland (July 8).

LECTURER (highly qualified physical chemist preferably with some experience in polymers and/or ceramics) in MATERIALS SCIENCES to participate in an honours or ordinary degree teaching programme in materials science and physical chemistry—The Registrar, Rugby College of Engineering Technology, Beeston, Rugby (July 8).

LECTURER (insect physiologist with an interest in environmental physiology) in Zoology in the School of Biology—The Registrar, The University, Leicester (July 8).

LECTURER (preferably with an electrical or mechanical engineering background with experience in electronics) in BIOENGINEERING in the DEPARTMENT OF MECHANICAL ENGINEERING—The Registrar, University of Strathclyde, George Street, Glasgow, G1 (July 8).

CHAIR OF STATISTICS AND COMPUTING SCIENCES at Royal Holloway College—The Academic Registrar, University of London, Senate House, London, W.0.1 (July 10).

COMPUTER OFFICER in the CHIEFS COMPUTING OFFICE to assist in the development and maintenance of the software required to help with the University's KDF 9 computer and to help with the systematic documentation of library programmes and other facilities available to users—The Registrar, The University, Nottingham (July 10).

LECTURER or ASSISTANT LECTURER (with broadly based geological training and research experience in one or more of the fields of X-ray crystallography and/or X-ray diffraction, X-ray spectrometry or clay mineral studies) in the DEPARTMENT OF GEOLOGY—The Deputy Secretary, The University, Southampton (July 10).

RESEARCH ASSOCIATE/SENIOR RESEARCH ASSOCIATE in the fields of History of Education or Philosophy of Education—The Assistant Registrar (B), University of Birmingham, 50 Wellington Road, Birmingham, 15 (July 10).

SENIOR LECTURER (with a higher degree and appropriate research, teaching and/or industrial experience) in PHYSICAL CHEMISTRY—The Registrar, Technical College, Sunderland, Co. Durham, quoting Ref. No. 303/8/2 (July 10).

JUNIOR LECTURER (preferably with an interest in physiology) in ZOOLOGY—The Secretary, Trinity College (University of Dublin), Dublin 2, Republic of Ireland (July 14).

LECTURER (with particular research interests in the fragmentation of organic molecules under electron impact) in PHARMACEUTICAL CHEMISTRY AND STRUCTURAL CHEMISTRY—The Registrar, University of Bradford, Bradford, 7, quoting Ref. P80/L/20/M (July 14).

SENIOR SCIENTIFIC OFFICER (with a first- or second-class honours degree or Dip. Tech. or equivalent or higher qualifications in geology or physics and preferably some relevant postgraduate experience) at the Hydrological Research Unit for research in ground-water aspects of hydrology—The Establishment Officer, The Natural Environment Research Council, State House, High Holborn, London, W.C.1 (July 14).

ASSISTANT LECTURER (with special interests in quantitative and mathematical analysis of sociological data) in SOCIOLOGY—The Registrar, The University, Manchester, quoting Ref. 108/67 (July 15).

DEPUTY LIBRARIAN (of suitable academic and professional standing)—The Secretary of the University Court, The University, Glasgow (July 15).

LECTURER (Grade II) (with at least a good honours degree in science or a medical qualification) in HISTOLOGY; a RESEARCH ASSISTANT in EXPERIMENTAL PHYSIOLOGY; and a RESEARCH ASSISTANT in ORAL PHYSIOLOGY in the DEPARTMENT OF PHYSIOLOGY—The Registrar and Secretary, University of Bristol, Senate House, Tyndall Avenue, Bristol, 2 (July 15).

LECTURER or ASSISTANT LECTURER in PHYSIOLOGY—The Registrar, The University, Sheffield (July 15).

LECTURER (S) in the DEPARTMENT OF BACTERIOLOGY—The Secretary, University of Edinburgh, Old College, South Bridge, Edinburgh (July 15).

ASSISTANT LECTURER/LECTURER in EXPERIMENTAL or THEORETICAL PHYSICS—The Registrar, The University, Keele, Staffordshire (July 17).

SENIOR LECTURER/LECTURER in FLUXUS SCIENCES (Climatology and Geomorphology) in the School of Earth Sciences; and a LECTURER in CHEMISTRY in the School of Chemistry, Macquarie University, Sydney, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, July 17).

KINGFISHER POSTGRADUATE STUDENT in TECHNOLOGY—Prof. D. Downon, Department of Mechanical Engineering, The University, Leeds, 2 (July 23).

LECTURER (S) (preferably with special qualifications in mineralogy and structural geology) in the DEPARTMENT OF GEOLOGY, University of Ibadan, Nigeria—The Inter-University Council, 33 Bedford Place, London, W.C.1 (July 28).

SENIOR LECTURER and a LECTURER (honours graduate in mining engineering with either subsequent metalliferous mining experience or research or practical experience in the field of rock mechanics) in MINING ENGINEERING;

and a LECTURER (with an honours degree in metallurgical engineering and a particular interest in extractive metallurgy) in PRODUCTION METALLURGY at the University of Queensland, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia, July 28).

LECTURER (S) in CHEMISTRY at Victoria University of Wellington, New Zealand—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, July 30).

CHAIR OF ORTHOPAEDIC SURGERY at the University of Singapore—The Inter-University Council, 33 Bedford Place, London, W.C.1 (July 31).

HEAD (with an honours degree in physics or a closely relevant science and able to co-ordinate the research programme of a department which is concerned with the application of the physical sciences to problems associated with many aspects of milk production and the utilisation of milk products) of the PHYSICS DEPARTMENT—The Secretary, National Institute of Research in Dairying (University of Reading), Shinfield, Reading, Berkshire, quoting Ref. 67/8 (July 31).

JUNIOR LECTURER/LECTURER in BOTANY at Rhodes University, Grahamstown, South Africa—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (South Africa and London, July 31).

LECTURER/ASSISTANT LECTURER (with experience in comparative neurophysiology and/or ultrastructural research) in the DEPARTMENT OF ZOOLOGY and COMPARATIVE PHYSIOLOGY—The Assistant Registrar (S), University of Birmingham, P.O. Box 363, Birmingham, 15 (July 31).

LECTURER/JUNIOR LECTURER in PHILOSOPHY at Rhodes University, Grahamstown, South Africa—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (South Africa and London, July 31).

LECTURER (S) in the DEPARTMENT OF PSYCHOLOGY at the University of Melbourne, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (July 31).

RESEARCH STUDENT (honours graduate in oceanography, physics, mathematics or meteorology) to participate in a programme involving the study of air-sea interaction processes—The Registrar, The University, Liverpool 8, quoting Ref. BV/85 (July 31).

SENIOR ASSISTANT in RESEARCH in the DEPARTMENT OF GEOLOGY—The Secretary, Faculty of Geography and Geology, The University, Sedgwick Museum, Downing Street, Cambridge (July 31).

ASSISTANT LECTURER or LECTURER in the DEPARTMENT OF INORGANIC, PHYSICAL AND INDUSTRIAL CHEMISTRY—The Registrar, The University, Liverpool, quoting Ref. BV/82 (August 1).

LECTURER (with a research interest in space physics and preferably research experience in gaseous ion physics) in REMOTE PHYSICS—The Assistant Registrar (S), University of Birmingham, P.O. Box 363, Birmingham, 15 (August 15).

TEACHING FELLOW in INORGANIC or PHYSICAL CHEMISTRY at Rhodes University—The Secretary-General, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1, or The Registrar, Rhodes University, Grahamstown, South Africa (South Africa, August 15).

BOYD BAXTER CHAIR OF BIOLOGY—The Secretary, Queen's College, Dundee, Scotland (September 2).

PATHOLOGIST in the MUFFIELD UNIT FOR LABORATORY ANIMAL PATHOLOGY to work in the field of experimental pathology—The Secretary, University of Edinburgh, Old College, South Bridge, Edinburgh (September 15).

PROFESSOR OF AGRICULTURAL SYSTEMS AND ORGANIZATION—The Registrar (Room 20, O.R.B.), The University, Reading (September 30).

PROFESSOR OF CROP PRODUCTION—The Registrar (Room 20, O.R.B.), The University, Reading (September 30).

PROFESSOR OF HORTICULTURE—The Registrar (Room 20, O.R.B.), The University, Reading (September 30).

CELL BIOLOGIST (with a good honours degree and postgraduate experience, and preferably experienced in animal cell, tissue or organ culture) in the BIOPHYSICS GROUP, to engage in a programme of mammalian cell culture and experimentation based on existing facilities, and to develop and control a new cell culture unit, planned for the immediate future—The Administrator, Medical Research Council Radiobiological Research Unit, Harwell, Didcot, Berkshire, quoting Ref. GJN/8/3.

EXPERIMENTAL PATHOLOGIST—The Administrator, Radiobiological Research Unit, Medical Research Council, Harwell, Didcot, Berkshire, quoting Ref. BEH 4/21.

HEAD of the DEPARTMENT OF ELECTRONIC AND ELECTRONIC ENGINEERING—Clerk to the Governing Body, Borough Polytechnic, Borough Road, London, S.E.1.

LECTURER in CHEMICAL ENGINEERING—The Registrar, University of Strathclyde, George Street, Glasgow, G1, quoting Ref. 47/87.

LECTURER (graduate in mechanical engineering with an interest in materials) in MECHANICAL ENGINEERING; and a LECTURER (graduate in metallurgy or physics and preferably a knowledge of ceramics) in MATERIALS SCIENCES—The Secretary, Sir John Cass College, Whitechapel High Street, London, E.1.

MASTER to teach PHYSICS to at least "A" level and preferably to University Scholarship standard—The Headmaster, School House, Tonbridge, Kent.

MICROBIOLOGIST (graded S.O./S.S.O.) (with a first- or second-class honours degree, Dip. Tech. or equivalent or higher qualification in an appropriate subject, and for S.S.O. at least three years postgraduate experience) in the BIOMODIFICATION DIVISION which is interested in the detoxification and nutritional improvement of tropical foods by fermentation—The Administration Officer, Tropical Products Institute, 56/58 Gray's Inn Road, London, W.C.1.

POSTDOCTORAL RESEARCH FELLOW (with training in zoology, cell biology, microbiology or biochemistry) to join a team studying the invasive mechanism of cancer cells—The Assistant Registrar, The University of Birmingham, P.O. Box 363, Birmingham, 15.

RESEARCH ASSISTANT (graduate or with a qualification of equivalent standard) to join a small unit working on hypothalamic control of gonadal development in birds—Dr. B. K. Follett, Department of Zoology, The University, Leeds, 2.

RESEARCH ASSISTANT (with a degree in biochemistry or microbiology) for work on the large-scale isolation of enzymes—The Secretary, University College London, Gower Street, London, W.C.1.

RESEARCH ASSISTANT (with a good honours degree in microbiology or a related subject) to investigate the antigens of mycoplasmas—The Secretary, Lister Institute of Preventive Medicine (University of London), Chelsea Bridge Road, London, S.W.1.

RESEARCH FELLOW at the Institute of Sound and Vibration Research for fundamental study of subjective ratings of industrial noise—The Deputy Secretary, The University, Southampton.

RESEARCH SCIENTIST, PALYNOLOGIST (with a degree in geology and/or botany at the doctorate level with specialization in palynology and preferably

experience in the stratigraphic applications of palynology and a knowledge of general botany and plant ecology) at the Institute of Sedimentary and Petroleum Geology in Calgary to carry out investigations on pollen and spores in Mesozoic rocks and to advise on their stratigraphic significance—Biophysical Sciences Program, Public Service Commission of Canada, Ottawa 4, Ontario, Canada, quoting Ref. No. 67-115-19.

## REPORTS and other PUBLICATIONS

(not included in the monthly Books Supplement)

### Great Britain and Ireland

- Northern Ireland: Ministry of Agriculture. Leaflet No. 77: The Installation, Maintenance and Operation of Milking Machines. Pp. 8. (Belfast: Ministry of Agriculture, 1967.) [105]  
 World Directory of Research Workers in Vertebrate Reproduction. Edited by Donn Casey, assisted principally by Isabel Prime. Pp. x+174. (Cambridge: Reproduction Research Information Service, Ltd., 1967.) 70s.; \$18. [105]  
 British Museum (Natural History). Economic Leaflet No. 6: Plantar Beetles. Pp. 8. 4s. Economic Leaflet No. 8: Carpet Beetles. Pp. 3. 3d. (London: British Museum (Natural History), 1967.) [105]  
 The Kent Incorporated Society for Promoting Experiments in Horticulture. Annual Report of the East Malling Research Station, Maidstone, Kent, 1st October 1966 to 30th September 1966 (Fifty-fourth Year). (ASO). Pp. xxiii+250. (Maidstone: East Malling Research Station, 1967.) 21s.; \$8. [105]  
 Admiralty Marine Science Publication No. 12: Hydrographic Observations in North Channel, Irish Sea, H.M.S. Scott, April 1963. By John Harvey and Sinclair Buchan. Pp. 10+12 figures. (London: Hydrographic Department, Ministry of Defence, 1967.) 12s. 6d. [105]  
 British Antarctic Survey. Scientific Reports, No. 58: An Ostracod Fauna from Halley Bay, Coats Land, British Antarctic Territory. By Dr. J. W. Neale. Pp. 50+4 plates. (London: British Antarctic Survey, 1967.) 24s. net. [105]  
 Annual Report of the British Iron and Steel Research Association for the year ending December 31, 1966. Pp. 103. (London: British Iron and Steel Research Association, 1967.) [115]  
 Civil Service Commission. Annual Report 1966 for the period 1st January to 31st December being the Hundredth Report of the Commissioners. Pp. 48. (London: H.M. Stationery Office, 1967.) 6s. net. [125]  
 Office of Health Economics. Alive to Forty-Five. Proceedings of a Symposium held at the College of General Practitioners, London, Sunday, 27 November, 1966. Edited by George Teeling-Smith. Pp. 36. (London: Office of Health Economics, 1967.) 7s. 6d. [125]

### Other Countries

- Rubber Research Institute of Malaya. R.R.I.M. Planting Manual No. 12: Rainfall in Malaysia: a Study of its Occurrence, with Tables of Probability of Rainfall at Selected Stations, and an Introduction to Hydrology in Rubber Plantations. By P. R. Wycheley. Pp. 85. (Kuala Lumpur: Rubber Research Institute of Malaya, 1967.) 2 Malaysian dollars. [95]  
 United States Department of the Interior: Geological Survey. Geophysical Abstracts, No. 243 (March 1967). By James W. Clarke, Dorothy B. Vitallano, Virginia S. Neuhoff, and others. Pp. iii+189-294. \$0.35. Bulletin 1198-G: Copper Mooses as Indicators of Metal Concentrations. By Hansford T. Shackleton. Pp. iii+18. \$0.15. Bulletin 1244-D: Correlation of Upper Triassic and Triassic(?) Formations between Southwestern Utah and Southern Nevada. By Richard F. Wilson and John H. Stewart. Pp. 20. \$0.15. Water-Supply Paper 1819-I: Ground-Water Development in the High Plains of Colorado. By Arnold J. Boettcher. With a section on Chemical Quality of the Ground Water by Robert Brennan. Pp. iii+23+plates 1-3. (Washington, D.C.: Government Printing Office, 1966 and 1967.) [105]

- Australia: Commonwealth Scientific and Industrial Research Organisation. Soil Publication No. 24: Soil Development in Relation to Stranded Beach Ridges of County Lowan, Victoria. By G. Blackburn, R. D. Bond and A. R. P. Clarke. Pp. 44+map. (Melbourne: Commonwealth Scientific and Industrial Research Organisation, 1967.) [105]  
 Annals of the New York Academy of Sciences. Vol. 141, Article 1: Biological Actions of Dimethyl Sulfoxide. By C. D. Leake and 162 other authors. Pp. 1-671. (New York: New York Academy of Sciences, 1967.) [105]  
 American Museum Novitates. No. 2270 (October 27, 1966): A New Subspecies of *Icterus icterus* and other Notes on the Birds of Northern South America. By William H. Phelps, Jr., and Ramón Avelledo H. Pp. 14. No. 2284 (March 10, 1967): New Subspecies and Records of Birds from the Karimn Basin, New Guinea. By J. M. Diamond. Pp. 17. (New York: American Museum of Natural History, 1966 and 1967.) [105]  
 Australia: Commonwealth Scientific and Industrial Research Organisation. Annual Report of the Animal Research Laboratories, 1966-66. Pp. 192. (Melbourne: Commonwealth Scientific and Industrial Research Organisation, 1967.) [105]  
 Bulletin of the American Museum of Natural History. Vol. 185, Article 4: Results of the 1968-1969 Gilliland New Britain Expedition. 4: Annotated List of Birds of the Whiteman Mountains, New Britain. By E. Thomas Gilliland and Mary Leeroy. Pp. 173-216. (New York: American Museum of Natural History, 1967.) \$1.50. [105]  
 United States Department of the Interior: Geological Survey. Water-Supply Paper 1806-B: Determination of Strontium-90 in Water. By J. O. Johnson and K. W. Edwards. Pp. iii+10. (Washington, D.C.: Government Printing Office, 1967.) \$0.15. [115]  
 Proceedings of the United States National Museum, Smithsonian Institution. Vol. 121, No. 3575: Some Bathyal Polynoids from Central and Northeastern Pacific (Polychaeta: Polynoidae). By Marian H. Pettibone. Pp. 16. Vol. 121, No. 3579: Valid Zoological Names of the Portland Catalogue. By Harold A. Rehder. Pp. 51. Vol. 121, No. 3580: The Myodocopid Ostracod Families Philomedidae and Pseudophilomedidae (New Family). By Louis S. Kornicker. Pp. 35+1 plate. Vol. 122, No. 3581: Classification of the Western Hemisphere Belontiids (Homoptera: Cicadellidae). By H. Derrick Blocker. Pp. 56. Vol. 122, No. 3584: The Brindley Sea Mink, with Taxonomic Notes. By Richard H. Manville. Pp. 12. (Washington, D.C.: United States National Museum, Smithsonian Institution, 1966 and 1967.) [115]  
 Museum of Comparative Zoology, Harvard University. Annual Report 1965-1966. Pp. 49. Breviora. No. 261 (31 March, 1967): The *Mesochorus* Group of the Lizard Genus *Asolis* in Hispaniola. By Richard Thomas and Albert Schwartz. Pp. 27. No. 262 (31 March, 1967): A Phylogenetic Survey of Molluscan Shell Matrix Proteins. By Michael T. Ghiselin, Ron T. Degens, Derek W. Spencer and Robert H. Parker. Pp. 25. No. 263 (31 March, 1967): The Hydroid of *Vesicocystis forbesi* (Anthomedusae, Tubulariidae). By Anita Brindmann-Voss. Pp. 10. No. 264 (6 April, 1967): The Chanares (Argentina) Triassic Reptile Fauna. 3: Two New Gomphodonts, *Mesocynodontis paschalis* and *M. teruggii*. By Alfred Sherwood Romer. Pp. 25. No. 265 (6 April, 1967): New Land-Locked Fish Species of the Genus *Galeosoma* from North Auckland, New Zealand. By R. M. McDowall. Pp. 11. No. 266 (6 April, 1967): A New Species of *Varicorhinus* from the Caribbean Sea (Mollusca: Bivalvia: Veneridae). By Kenneth Jay Boss. Pp. 6. (Cambridge, Mass.: Museum of Comparative Zoology, Harvard University, 1967.) [115]  
 State of California. The Resources Agency: Department of Fish and Game Fish Bulletin No. 135: Ecological Studies of the Sacramento-San Joaquin Delta. Part 2: Fishes of the Delta. Compiled by Jerry L. Turner and D. W. Kelley. Pp. 106. (Sacramento: Department of Fish and Game, 1966.) [115]  
 Metropolitan Life Insurance Company. Statistical Bulletin, February 1967 (Vol. 48): Geographic Variations in Longevity After Age 65. Fatal Accidents Increasing Among Men at the Working Ages. The Problem of Arthritis. Death Claim Payments Higher in 1966. Pp. 12. (New York: Metropolitan Life Insurance Company, 1967.) [115]  
 Organisation for Economic Co-operation and Development. Methods and Statistical Needs for Educational Planning. Pp. 363. 35 francs; 50s.; \$8.50. Basic Statistics of Energy, 1961-1966. (Statistical Bulletin). Pp. 290. 20 francs; 20s.; \$5. (Paris: Organisation for Economic Co-operation and Development; London: H.M. Stationery Office, 1967.) [115]

## HOW TO BUY NATURE

Volumes start in January, April, July and October, but subscriptions may begin with any issue

The direct postal price per subscription for one or two copies of NATURE each week is:

\*12 MONTHS (52 issues and 4 indexes)

Great Britain and Eire	£14.0.0 each
United States of America	.. (by air freight) .. \$44 each
Canada	.. (by air freight) .. \$47.80 each
Elsewhere overseas by surface mail	£13.15.0 each

(Charge for delivery by air mail on application)

\*Shorter periods pro rata. (Minimum three months)

### MULTIPLE SUBSCRIPTIONS

For subscribers who take more than two copies of NATURE each week these reduced annual rates are offered:

12 MONTHS (52 issues and 4 indexes)

Number of Copies	GB & Eire	U.S.A.	Canada	Elsewhere (surface mail)
	Each	Each	Each	Each
3-5	£13.10.0	\$42	\$46.00	£13.10.0
6-11	£12.15.0	\$40	\$43.50	£12.15.0
12 or more	£12.0.0	\$38	\$41.70	£12.0.0

Multiple subscriptions must run concurrently. Every copy will be posted separately, and for speed of delivery each subscription can be addressed to a different individual, or department at the same address. (ZIP essential for U.S.A.)

Editorial and Publishing Offices of "NATURE"

MACMILLAN (JOURNALS) LIMITED

4 LITTLE ESSEX STREET, LONDON, W.C.2.

Telephone Number: 01-836 6633. Telegrams: Phuss London W.C.2.

Subscription Department

MACMILLAN (JOURNALS) LIMITED

BRUNEL ROAD, BASINGSTOKE, HANTS

Telephone Number: Basingstoke 5431

Annual subscription: United Kingdom and Eire £14, U.S.A. \$44

(air freight), Canada \$47.80 (air freight), all other countries

£13 15s. (surface mail), payable in advance.

Advertisements only should be addressed to

## COMPUTERS ON THE LINE

PLAINLY it is more than just a coincidence that the British and the American Governments should be bothered at the same time about the problems of arranging that computers should be enabled to communicate with each other by means of the conventional telephone system. By now, there has been talk enough of how computers will, one of these days, enter into the detailed administration of people's lives; how they will cash cheques, make airline bookings and rummage through bibliographies in some distant electronic library. They will so clearly assist the processes of communication that they are bound to be an alternative to many forms of communication by telephone and telegraph. It is only natural that the problems of how the new technology will marry with the old have come to a head in the United States and in Britain at roughly the same time.

This said, there are significant and even characteristic differences. On both sides of the Atlantic, of course, organizations at present established in the handling of telephone and telegraph traffic are anxious to know that they should have a share in the data transmission to and from computers. In Britain, the General Post Office is securely placed, with its effective monopoly on internal telecommunications; although it is theoretically possible for would-be independent operators to apply for licences to set up communications systems of their own, the chances of this happening are small. In the circumstances, it is not surprising that the question now being argued in Britain is whether the Post Office should be allowed to graft on to its communications network enough computer capacity to be able to offer a computing service to the public as a whole. With the approval by the House of Commons of the Data Processing Services Bill on July 4, it is only a matter of months before such a service is launched. In the United States the relationship between the communications carriers and the computing services are necessarily more complicated, and in any case the Federal Communications Commission, which is supposed to regulate the use of telecommunications, is going through a bad spell of indecision. It may, for example, have to allow the Western Union company, recently losing business on telegrams, to provide an integrated data processing system by means of its communications network. As yet, however, nobody knows whether AT & T, which is effectively in charge of the telephone system in the United States, would then follow suit. But the computer manufacturers are almost as concerned as the network operators to see some equitable solution worked out.

Whatever may be said in opposition to the plans the Post Office has been making, there is no denying that it has moved quickly and decisively. Although

there has been talk of a public data processing network for two years or more, it is only in the past few months that the Post Office has made known what it plans to do. To begin with, it plans to sell time on computing machinery already installed within the Post Office system, and it is not surprising that critics of the plan have been paying suspicious attention to the fact that 50 per cent of the capacity of the computers already in service with the Post Office is at present unused. The plan is to install enough computer machinery by the end of the decade to convert the Post Office into what will be the largest computer bureau in Britain. What happens after that is anybody's guess, but it is not hard to see why those who at present operate computer systems are apprehensive.

In principle, however, there is nothing inherently outrageous in what the Post Office plans to do. If it can offer an efficient data processing network, and if it can compete effectively yet fairly with commercial organizations, its intervention could be an asset. The snags, most of which have been clearly recognized in several constructive debates on the subject in the House of Commons, lie principally in the way in which the Post Office would set about the organization of its computer network. The obvious but somewhat abstract danger that a Post Office data processing network would allow the Government to keep an uncomfortably close watch on the way in which commercial organizations run has been acknowledged, and the Data Processing Bill now enjoins the Post Office to see that material in the course of being processed is kept confidential to those who own it.

A more serious problem is that of making sure that the Post Office does not compete unfairly with the commercial operators, possibly by using its great financial resources to undercut competitors. The British Government has been ready to acknowledge that there is a risk of unfair competition, and it has promised that the Data Processing Service will be operated as an independent unit within the Post Office. Unfortunately, however, good intentions are not guarantees, and if the Post Office persists in saying that computing machinery should be amortized over a period of ten years when commercial operators make less cheerful assumptions about the durability of their investments, it may well be able to charge less for data processing than its competitors. The trouble here, of course, is that there is no obvious means by which the charges made by the Post Office will be open to scrutiny and control. When the Post Office becomes an autonomous nationalized industry and not a part of the Civil Service as at present, there will be fewer opportunities than at present for objective criticism of the charges which are levied. And, however keen

civil servants may be to see that the Post Office operates legitimately, their efforts are bound to seem unconvincing to outsiders. In other words, the Government may not yet have recognized all the difficulties of allowing a nationalized industry to compete freely with private companies.

These, however, are immediate problems. Ten years from now, they could easily seem trivial and even pedantic. By then, time sharing computers will be commonplace. Businesses of all kinds will be dependent on computers not merely for huge parcels of data processing but for the solutions of smaller problems as well. This is why the enterprise of the Post Office in moving quickly into data processing should not tempt it to overlook its primary responsibility for efficient communications. Some computer users complain that the Post Office network is overloaded, and that more people would be using computer services already if there were more land lines available. Although the Post Office has been able to multiply the number of computer terminals by three in the past two years, and although complaints about the service now being offered may be exaggerated, it is hard to be confident that planning for the more distant future is being undertaken on a sufficiently ambitious scale.

What, for example, will be the contribution of lasers to communications in the future? What kinds of switching systems will be necessary to handle the gigantic loads on the telecommunications system ten years from now? What use will by then be made of satellites for domestic as well as international communications? Will it make sense to continue operating telephone networks without pulse code modulation? The research programme which the Post Office has in hand seems only inadequately to match the real and urgent needs which are now apparent. It is not reasonable to object that the Post Office is proposing to take a hand in data processing, but there will or should be trouble if it neglects to pursue the improvement of the communications network with the vigour which circumstances require. Even the most cursory examination of the way in which the Federal Communications Commission has been dazzled and even bewildered by the prospect of radically new means of communications should serve to show the Post Office that the problems are not all technical and that few of them are simple.

## COMMITTEE AND AEC

THE relationship between the Joint Congressional Committee on Atomic Energy and the Atomic Energy Commission in the United States has changed a great deal since the time, a decade ago, when the annual examination of the AEC budget seemed more a public spectacle of enmity than an orderly contribution to good government. At the beginning, of course, the AEC was prevented by a combination of arrogance and innocence from learning quickly how to get on

with Congress. The Joint Committee also had to make its reputation in what must then have seemed an exceedingly difficult technical field—and in the event it has succeeded so well that it has not merely become a power in the land on its own account but has also become a model to other committees of Congress which have somehow to make themselves effective critics in technical fields.

The American Constitution is a great help, of course. Congress is as jealous of its independence from the Administration as the British House of Commons is jealous of its independence of the monarchy. In Washington, one result is that the committees of Congress responsible for the detailed scrutiny of legislation are invested with all the prestige and authority that Congress has to muster. Even if the chairman of a committee, who may find that he owes his appointment to nothing but seniority, turns out to be a wayward eccentric, Congress as a whole will not willingly let the Administration make a monkey of him. The committees which make the pace in Washington, however, are those which can somehow establish an authority of their own. The Joint Committee on Atomic Energy has done this, and its success derives almost exclusively from its diligence. Since the early fifties it has been building up an enviable reputation for understanding of and discernment in the operations of the AEC. A decade ago it was largely responsible for persuading the AEC and the other government agencies concerned that there are more problems in regulating the safe use of radioactive materials than could be solved by setting rigid numerical limits for the kind of dose which should not be exceeded. By now, the committee has become expert on a host of technical matters. It can be relied on to know what the AEC is getting at when it says that one type of reactor is less promising than another. It can take a line of its own on the importance of plasma research. It has views on nuclear propulsion for rockets. Its competence has clearly won the respect not merely of other committees of Congress but of the AEC as well.

How has all this come about? Committees elsewhere—the Select Committee of the House of Commons on Science and Technology, for example—should be asking this question. When the prestige of Congress is discounted, the secret of the Joint Committee's success is principally to be found in the way in which it has been able to employ a full-time staff of able people willing to devote themselves to a continuing study of one branch of government administration. One striking proof of how this works is that the man who was for several years the committee's chief of staff, Mr James T. Ramey, became three years ago a member of the AEC. But this, of course, is also a proof of how close has now become the relationship between the committee and the AEC.

But could it be that the relationship is now closer than it should be? There is certainly something in the view that a certain tension between congressional committees and agencies of the Administration is desirable as well as unavoidable. One danger is that

if a committee and the agency which it is supposed to superintend live too closely in each other's pockets, there will be no means of making sure that their combined attitude to the outside world is sound. Another is that a committee which is too knowledgeable and too winsome may find itself persuading a government agency to particular lines of development which become, in retrospect, unwise. In other words, there is a danger that too expert a committee might find itself able to exercise power without responsibility.

On the face of things, the Joint Committee tends towards errors of the second kind. Its report on this year's budget application by the AEC (see page 116) shows how carefully the committee picks over the details of the budget, subtracting a few thousand dollars here and there, and sometimes even adding a few thousand. On one view, this is a splendid illustration of the democratic control of public institutions. On another, it is a sign that Congress and the Administration are too closely entangled.

There is no reason to believe that the committee's work has been unreasonably intrusive in the recent past. On the contrary, the chances are that the prodigal needed to make accurate calculations of the cost of running particle accelerators before constructing them, and the campaign for better regulations to protect the health of uranium miners, have helped to make the policies of the AEC more sensible. But what if the question should arise of whether the AEC in its present form should continue to exist? Would the Joint Committee take kindly even to the much more modest proposal that responsibility for high energy physics might be transferred to the National Science Foundation? There is bound to be a suspicion that the Joint Committee, for all its expertise, would resist too radical a change. The trouble is that the time has probably come for a detailed re-examination of the function of the AEC. The best proof the committee could give of its resolution would be to begin an investigation off its own bat.

## PINK SPOTS GALORE

It is now five years since Friedhoff and Winkle first suggested that the urine of schizophrenic patients may be characterized by something which yields a pink spot in a fairly standard chromatographic procedure (*Nature*, 194, 897; 1962) and the interval has been crowded with ups and downs. At the beginning, of course, there was great excitement. The finding of the pink spot chimed in well with an accumulation of evidence to suggest that the metabolism of schizophrenic patients is biochemically distinctive. Five years ago, however, it must have seemed almost too much to hope for that the appearance of a single chemical substance, identifiable by a comparatively simple technique, might serve to distinguish a substantial proportion—ten per cent or so—of those who suffer from schizophrenia. Obviously a simple pink

spot would have great value in diagnosis, although this was almost the least exciting of many possibilities. Naturally enough there was talk of seeking out people who might be biochemically prone to schizophrenia, but in whom the symptoms had not become overt. But there was also every reason to hope that when the chemical responsible for the pink spot had been properly identified, a means would have been provided for understanding something of the biochemical character of schizophrenia, and possibly of its causation as well. No wonder, then, that hats were thrown in the air when, in 1963, it seemed as if the chemical responsible for the pink spot might be  $\beta$ -3,4-dimethoxyphenylethylamine, or DMPE for short, for it is entirely plausible that such a chemical could have arisen by an error of tyrosine metabolism and that its pharmacological effect might be something like schizophrenia.

Those happy days now seem a long way off. Doubts about the identification of the pink spot with DMPE persisted from the beginning. One difficulty is the obvious problem of working with tiny quantities of material. In circumstances like these, chemical identification is necessarily rather indirect. But there were more serious problems bound up with the difficulties of knowing whether subjects examined for pink spot in the urine were schizophrenic or otherwise, for this is not a field in which diagnosis is easy. Predictably it was not long before apparently normal people were found to yield pink spot. Yet another difficulty was that the substance responsible might be produced by the metabolism of some drug used in the treatment of patients. Finally, a year ago it was demonstrated more or less conclusively that whatever pink spot might be, it was certainly not DMPE. The tale has now taken another turn with the report that the substance responsible is probably *p*-tyramine, and that the material which is responsible for the schizophrenic pink spot also occurs in urine from many patients with Parkinson's disease (see this issue, page 132). Boulton, Pollitt and Majer seem to be quite confident that the pink spots they have been able to find in the urine of patients with schizophrenia and Parkinson's disease are caused by *p*-tyramine. With the benefit of hindsight, it now seems likely that the schizophrenic pink spots reported in recent years may often have been caused by *p*-tyramine and not DMPE. Moreover, while the difficulties of diagnosis must still leave doubt about the association of the pink spot with schizophrenia, it is much more probable that it is causally related to Parkinson's disease. Already speculation has begun about the ways in which errors of metabolism in parkinsonism may account not merely for the *p*-tyramine but for the abnormally high concentrations of dopamine in some brain tissues from patients with Parkinson's disease. The suggestion that there may be a biochemical link between some forms of schizophrenia and Parkinson's disease will not come as a complete surprise. This said, it is bound of course to be a long time before the precise significance of the pink spot is clear, but it is something important gained if its chemical identity is now assured.

## NEWS AND VIEWS

### AEC In Plenty

THE programme of the US Atomic Energy Commission for the new fiscal year has received its customary and predictable blessing from the Joint Committee on Atomic Energy. In the committee's report to Congress, based on a series of hearings which began at the end of January and lasted for seven weeks, the committee has suggested some modest additions to the AEC's own version of its operating budget and has pared some \$7 million from the request for capital funds in the year ahead. If the committee has its way, and there is hardly any chance that it will fail to do so, the AEC will have a total of \$2,634 million to spend, \$2,165 million of it on operating expenses.

Both the Joint Committee and the AEC seem cheerful about the development of civil nuclear power in the United States. The committee is proposing that the AEC should have \$484 million to spend on the development of reactors, more than a fifth of it on systems for naval use. The development of power reactors will cost \$119 million in the fiscal year ahead, and the committee pats the AEC on the back for deciding to stop work on a number of reactor types which have come to seem unpromising now that utility companies in the United States are placing orders for reactors almost as quickly as they can. Among the casualties this year are the beryllium oxide reactor experiment and a design involving heavy water as moderator and an organic liquid as coolant.

The Joint Committee has also accepted the view of the AEC that the time has come for a considerable increase of the amount spent on basic physics of various kinds. Plasma physics will get an extra 15 per cent, or a total of \$28 million, in 1968, which reflects the view now current among plasma physicists that the time has come for a deliberate increase of effort in this field. There is also plenty of money for accelerators, and in particular a cool \$50 million for the meson factory which is to be built at Los Alamos.

### Oxford In Revolt

THROUGHOUT the months of protest since Mr Anthony Crosland increased university fees for overseas students, it has been hard to find a university prepared to support its principles with hard cash. In the end, Oxford remained true to its traditions of eccentricity and down-right dilatoriness. Last week, over six months after Mr Crosland announced the increases, Congregation decided that it did not agree. By 43 votes to 27, the university parliament rejected a motion from the Hebdomadal Council to raise fees from £100 to £150. Even the council's recommendation was something of a rebellion, as Mr Crosland wants to see fees at £250 per year.

What will happen next is still not clear. The decision was apparently taken in an atmosphere approaching open revolt—Mr F. T. B. Millar of Queen's College

suggested that the UGC should have resigned, and Professor Max Beloff regretted that he was unable to impeach Mr Crosland. The cost to Oxford will be £80,000 this year and £120,000 in later years. As a gesture towards payment, a fund has been started by Professor Dorothy Hodgkin of Somerville, Mr George Bennet of Lincoln and Mr R. H. C. Davis of Merton. Each has contributed £5 to the fund, and is busy getting signatures for an appeal and further contributions to the fund. However strongly Oxford dons feel about their decision, though, the fund is hardly likely to soften the blow very much unless wealthy foundations or colleges are prepared to weigh in with substantial contributions.

The Department of Education and Science has nothing to say on the subject. So far as it is concerned, the situation was covered by the original announcement, which assumed that university grants for the next five years would take account of fee income at a rate of £250 per year for each overseas student. Universities charging lower fees than this have a perfect right to do so, but have to find the money themselves. Other universities may feel bitter that once again Oxford's wealth has allowed it more freedom than recent foundations can afford. They may also complain that Oxford will now have first refusal of all the most able candidates from overseas. Oxford itself can claim that its elaborate system of government, often defended on the grounds that it is democratic, has reached a decision more daring than most of its critics would have believed possible. Whether the university can afford to put it into action remains to be seen.

### More about Data Processing

WHEN the Post Office (Data Processing) Bill reached its report stage in the House of Commons on July 4, it was clear that the alarms of the Bill's opponents had not been silenced by the committee stage. The objections to the Bill were much the same as they had been when it was first introduced. First, Mr David Price moved an amendment which would force the Postmaster-General to keep a separate account for the Data Processing Service. He feared that the service would be run at a loss, and subsidized by the other postal services, providing the independent computer bureaux with unfair competition. Undertakings that this would not happen were no equal of a protection in law, he thought. Postmaster-Generals come and go, Mr Price said, and not all of them would feel obliged to conform to Mr Short's undertakings.

Mr Short, the Postmaster-General, denied that financial jugglings of the sort the Opposition were suggesting were even possible. Parliament and the press would see to that—he was always open to challenge. Sir Harry Legge-Bourke wondered if this will still be true when the Post Office is reorganized as a public corporation instead of a government department. The clause, however, was withdrawn.

Sir Harry went on to move an amendment which sought to establish that the first duty of the Post Office was to provide data transmission facilities for others—the service, he said, should not be allowed to diminish in the Postmaster-General's mind the need to press on with telecommunications and the ordinary work of the Post Office. Mr Short gave more assurances, and the amendment was withdrawn.

Mr J. Osborn was afraid that the Bill would open the door to commercial espionage, and moved an amendment to widen the clause covering secrecy of information. Mr Short said the intention of the amendment was simple, but it was unworkable. Once again the amendment was withdrawn, and finally the report stage was completed and the Bill was read for the third time.

## A Louder Voice for Technicians

The largest technicians' union in the world is in prospect with the recommendation by the executives of the ASoW and ASSET that the two associations should amalgamate. The ASoW is the Association of Scientific Workers, and ASSET is the Association of Supervisory Staffs, Executives and Technicians; on July 2 the two executives considered the report of a joint committee, and agreed unanimously that amalgamation would be in the best interests of their membership. Before the merging of the associations can go into effect, there must be a full ballot of the members, which will be preceded by a series of meetings at which the arguments can be put across. If the members agree with their executives, the association could be merged by February 1968.

The reasons for the amalgamation are not hard to find. With a joint membership which the executives claim, perhaps optimistically, at 80,000, the joint union will be both more powerful and more effectively organized than the two could hope to be alone. Not the least of its possessions will be the General Secretary of ASSET, Mr Clive Jenkins, who has been a thorn in the side of the British Government throughout the prices and wages freeze. Employers will have to face some tough battles if the merger goes through, but these will be as nothing compared with the situation if ASoW and ASSET take their arguments to a logical conclusion and start negotiations towards a merger with DATA, the Draughtmen's and Allied Technicians' Association. DATA has a membership of over 71,000, and is recognized as one of the most determined unions in Britain—employers would probably prefer the term intransigent. A full scale merger of this sort could ultimately lead to a membership of 250,000.

## Good Cheer for Neuro-biologists

It seems probable that neuro-biology will profit from the work of a sub-committee of the Science Research Council which has been making a survey of needs in this field in the past few months. One way and another, the sub-committee seems to have convinced itself that there are, in particular, shortages of neuro-anatomists and of biochemists wishing to pursue research in neuro-chemistry, and shortages of funds necessary for their support. One probable result is that the Biology Committee of the Science Research Council may commit itself, and the Science Research Council as well, to a deliberate policy of expansion in neuro-biology, sometimes even going as far as to suggest particular research projects. Another approach will be to provide courses by means of which professional scientists can become skilled in these fields. In this spirit, Professor J. Z. Young at University College, London, is hoping to provide courses in neuro-anatomy at University College, London, lasting from three to

twelve months if there is enough demand—and if the SRC will provide support. In much the same way, the SRC seems now to be at least half committed to a programme for the more generous support for animal behaviour—another of the four fields of research singled out for special study by the Biology and Biochemistry Committee.

These developments are potentially interesting as innovations of principle as well as for the practical benefits which they may bring. For one thing, these activities mark the continuing growth of the interest of the SRC in the biological sciences. For another, it may be an important precedent in the administration of British science that a public grant-giving agency should set out deliberately to stimulate the demand for grants in particular fields of study—this is entirely in line with the way that charitable foundations now seek to work, but public bodies have often been much more content to follow a passive policy. The interest of the SRC in neuro-biology will also raise again the question of how the Science Research Council should relate its work to that of the Medical Research Council, which supports research in neuro-biology. That question would be much easier to answer if the MRC were possessed of a more explicit strategy for the spending of money.

## A Committee for Hovercraft

By the apparently immutable rule that every new task implies a new advisory committee, the National Physical Laboratory is to have a hovercraft committee. The committee will tell the NPL what research is needed to support the development of hovercraft, including hovertrains, and how much money will be needed to carry it through.

The first chairman of the committee will be Mr M. A. L. Banks, who has just retired as the Deputy Chairman of the British Petroleum Company, and the members of the committee will be nominated by all the interested parties, including the Ministry of Defence, the NRDC, the Ministry of Transport, and an organization representing the firms licensed to manufacture hovercraft. Already there is promise of further working parties, to look after marine hovercraft, tracked hovercraft, or, indeed, as the announcement puts it, "any other aspect of the subject where there is need".

## Road Research

Quite suddenly, it seems, the Road Research Laboratory has become a vital part of the planning of the Ministry of Transport. The proposals on road pricing which the Minister, Mrs Barbara Castle, is studying will rely heavily on work done by the laboratory. The recent legislation which compels all new cars to have seat belts is also a result of the laboratory's work. The philosophy—an entirely sensible one—seems to be that it is more profitable to minimize injury when accidents do occur than to hope that by constant exhortation accidents can be banished altogether.

The report of the laboratory for 1965 and 1966 provides some examples of this approach. Collisions with conventional lamp standards produce severe damage, often almost cutting cars in half; but, by using a new type of break-away lamp standard, damage can be considerably reduced. Guard rails mounted along

motorways on weak steel posts can steer cars back on the right carriageway even at impact speeds of 70 m.p.h. or over. Again, damage to the vehicle is reduced, and the danger of head-on impacts with approaching cars is minimized.

Much of the work, of course, is not directly concerned with safety. The traffic section includes predictions of the number of vehicles on British roads up to the year 2010 (27 million by 1980, 40 million in 2010), and gives details of the traffic flows in towns and on the M4 motorway. It also describes the problem a driver faces when approaching a green light at high speed; if it changes to amber too late for him to stop, should he brake and risk skidding or accelerate and hope to be clear of the cross traffic? The dilemma is common enough, but does not seem to have been seriously studied before; the report suggests a solution based on a speed detector which will in some circumstances give fast drivers an extension of the green signal.

In addition, the report describes the problems of road building, both in temperate and tropical climates. One of the responsibilities of the laboratory is to provide technical aid for developing countries, where the development of roads is often an essential forerunner of economic development. Last week, the laboratory opened new buildings at Crowthorne in Berkshire and, for the first time since the war, the work of the laboratory is carried out on one site. The new buildings cost £3.5 million, which is also what the laboratory costs to run each year. The figure given in the Civil Estimates for support for traffic research in 1966 is £3.52 million, showing a sharp increase over the 1965 figure of £2.66 million.

## Detecting Turbulence

WHILE the causes of clear air turbulence remain obscure, it is clear that it is often associated with temperature gradients in the atmosphere. Recent work at Oxford and Reading Universities may offer a way of detecting the gradients, and, by inference, the turbulence. If this can be detected far enough ahead of aircraft, evasive action can be taken.

This, clearly, is the argument which has encouraged the Science Research Council to award a grant of £89,000 to Dr J. T. Houghton of the Clarendon Laboratory at Oxford and to Dr S. D. Smith of the Department of Physics at Reading. Together they have developed a radiometer which detects the infra-red radiation from carbon dioxide in the atmosphere, and the instrument is now being produced in its engineered form by Elliott Bros. (London), Ltd., of Frimley, near Aldershot. In its present form the radiometer will be used in an American satellite, called Nimbus D, to be launched by NASA in late 1969, and is intended to provide a world-wide survey of the temperature of the atmosphere up to about 30 miles. At different heights in the atmosphere, the carbon dioxide band occurs at different wavelengths, so that by choosing a certain wavelength a certain height can be studied by the instrument in the orbiting satellite. In the Nimbus experiment, the temperature of the atmosphere will be studied from cloud top height to about 30 miles, to an accuracy of about  $\pm 1^\circ\text{C}$ .

It is also hoped to develop the instrument for the detection of clear air turbulence. In this role, it would

be mounted in the front of the aircraft, scanning the region of the atmosphere ahead. By detecting temperature gradients, it might be possible to avoid regions of clear air turbulence. Dr Houghton believes that the range of the instrument could be 50 miles, not as great as the operators of supersonic transports might wish—they hope for a range of 100 miles—but better than nothing. The SRC certainly believes the instrument has a commercial future, and has asked the NRDC to consider further development of the design with an industrial firm.

## Rheumatism, Tractable and Otherwise

THE MRC Rheumatism Research Unit housed in the Canadian Red Cross Memorial Hospital at Taplow celebrated its twentieth anniversary last week. Although it had no dramatic announcements to make, it is proud of a steady advance in the treatment of the more tractable forms of rheumatism. The term itself includes any disease of the joints which causes pain and which is aggravated by movement. Professor Bywaters, honorary director of the unit, says that there were 83 different rheumatic conditions at the last count, ranging from sprains to degenerative conditions due to ageing, metabolic disorders such as gout, infective conditions such as rheumatic fever and arthritic diseases the cause of which is unknown.

The unit is chiefly concerned with the arthritic group of disorders, and the most promising line of research centres around the possibility that rheumatoid arthritis involves an immune reaction of the body to its own tissues. Certainly auto-immune reactions like these have been demonstrated in mice and can cause a syndrome similar in appearance to rheumatoid arthritis. But this is only one possibility. Some workers even claim to have found characteristic organisms in the synovia of patients with this disease, suggesting an infective mechanism, but this is in dispute. But there are certainly infective mechanisms in rheumatic fever, one of the more unpleasant possibilities following a sore throat. Over the years the treatment of rheumatoid arthritis has improved considerably, especially with children. Until recently, children with the chronic disease were confined to bed, which often made their condition worse. Nowadays treatment is designed to minimize deformity so that children can lead full lives when they recover—as in time they do. Splinting and physiotherapy play a part, as does the use of drugs to reduce pain and inflammation. Salicylates and corticosteroids are frequently used, but neither is free from side effects; corticosteroids in massive doses, for example, can control pain and inflammation but may cause a child to fail to grow in height. The problem is to weigh the advantages of treatment against the disadvantages of side effects.

## Fossil Fishes

Dr Alan J. Charig writes:

THE Linnean Society of London is marking the retirement of Dr Errol I. White as Keeper of Palaeontology in the British Museum (Natural History) and President of the Society with a special volume of articles mainly on fossil fishes, and five of the twenty papers therein were read at a one-day symposium on June 23. One striking feature of the paper by Professor E. Jarvik of

Stockholm on the lower jaws of dipnoans was that there appears to have been very little change in the dermal bone pattern since the Devonian, at least as far as can be told from a comparison of the fossil genera *Dipterus*, *Scaumenacia* and *Melanognathus* with the recent lungfishes. The dermal bone pattern of all dipnoans is quite distinct from that found in other vertebrates. Jarvik also emphasized the similarities between the Dipnoi and the Holocephali, autostylic jaw suspension and tooth-plates used for chewing and crushing, for example, although he did not claim that these necessarily implied a close phylogenetic relationship.

Dr Bobb Schaeffer of New York then attempted a new interpretation of osteichthyan vertebrae. He had examined both fossil and Recent material, bearing in mind that Gadow's classical "arcualia" theory (that, in all vertebrates, each vertebra originates from four pairs of cartilaginous blocks) had recently been demolished by E. E. Williams as far as the tetrapods were concerned. This, however, had raised more new questions than it had produced answers. In no living holostean or teleost is there any evidence of arcualia; neither is there any division of the sclerotome by the sclerocoel with subsequent resegmentation, as observed by Williams in the tetrapods. Experimental work is urgently needed.

Dr A. Ritchie of Sheffield described in great detail the rare and primitive ostracoderm *Ateleaspis tessellata*, a non-cornuate cephalaspid from the Lower Ludlovian (?) of the Midland Valley of Scotland, and concluded that this resembled the Norwegian *Aceraspis robustus* so closely—differing mainly in the outline and other details of the oral opening—that both species should be placed in the one genus *Ateleaspis*. One member of the audience, however, asserted that the Norwegian form was more advanced. In another fossil from the Middle Devonian of northern Scotland, the pytodont fish *Rhamphodopsis* Watson, Dr R. Miles of Edinburgh was able to demonstrate sexual dimorphism in the pelvic fins—the first time that this has been shown in any placoderm.

Evidence that will bring comfort to the proponents of continental drift has been gathered by Dr D. L. Dineley of Ottawa from the Knoydart Formation of Nova Scotia. The very same species occur in Nova Scotia and the Welsh Borderland: *Traquairaspis symondsii* in the Downtonian and *Peraspis crouchi* in the Middle Dittonian. Between these two in Nova Scotia occurs *Pteraspis whitei*, upon which a true biostratigraphical zone may be recognized; presumably this corresponds to the Lower Dittonian in Britain, containing *P. leathensis*. It is hoped that the establishment of palynological standards for Old Red Sandstone stratigraphy will soon make it possible to measure the dispersal rates of these ostracoderms.

## Active Sites of tRNA

from our Correspondent in Molecular Biology

THE recent determination of the base sequences of several specific transfer RNA molecules, and the discovery of rather extensive common features between them, has provoked strenuous efforts to localize the functional centres. These have for the most part not been overwhelmingly successful, but a number of interesting results have nevertheless emerged.

All the sequences so far determined are consistent with the "cloverleaf" model, based on maximum reasonable base pairing. There are in all cases three large loops, each of about seven unpaired bases. One of the loops apparently contains the anticodon, and it has been generally supposed that all the active sites reside essentially in them. It appears, however, that the common terminal sequence CCA is required for enzyme recognition, and evidence has accrued (most recently in an article by Stulberg and Isham (*Proc. US Nat. Acad. Sci.*, 57, 1310; 1967)) which bears out earlier work that the removal of this tail leads to overall changes of conformation.

A study by Adman and Doty (*Biochem. Biophys. Res. Commun.*, 27, 579; 1967) shows that the alanine acceptor activity of tRNA in the unfractionated state is destroyed on reduction of uracil residues. From the statistics of the process, assuming a random hit mechanism, it seems that no fewer than half the uracil residues must be reduced before the molecule is inactivated. Since the random hit assumption is very reasonable, it seems most likely that the enzyme recognition site in alanine tRNA contains no uracil, and evidence from optical rotatory dispersion indicates that the inactivation results from the breakdown of secondary structure.

A related approach by Lindahl (*J. Biol. Chem.*, 242, 579; 1967) involves irreversible thermal inactivation of tRNA, in respect of three separate functions: amino-acid acceptor activity, ability to incorporate adenylic acid as the chain terminus (a reaction catalysed by an enzyme for which all tRNA species are substrates) and specific attachment of the tRNA to ribosomes. At 90°C, the loss of activity is greatly accelerated by the presence of magnesium ions. Magnesium is known to catalyse the thermal hydrolysis of phosphodiester bonds and in its presence thus appears to be the chief cause of inactivation. Without magnesium, on the other hand, although some chain scission certainly occurs, the number of breaks is not sufficient to account for the loss of activity. Depurination and deamination are similarly ruled out as determining factors. Lindahl therefore concludes that particular heat labile residues must be involved, and the only such known to be present in tRNA are the dihydrouracils (DHU). If this interpretation is correct, then it appears that the DHU must be preserved intact for all three activities. These groups may therefore be thought to function as hinge points for the conformation. Lindahl also notes that valine-specific tRNA, which is the only species known to contain four DHU residues, is very rapidly inactivated in respect of acceptor activity, though less so for adenylic acid incorporation.

It may also be mentioned that a structural change evidently also occurs when tRNA binds its specific amino-acid. The most recent evidence to this effect is the observation (Kaji and Tanaka, *Biochim. Biophys. Acta*, 138, 642; 1967) that the aminoacyl-tRNA sediments more slowly, and therefore probably has a less compact structure, than unloaded tRNA. This recalls the earlier report by Lamborg and Zamecnik, based on optical rotatory dispersion, that some helical structure appears to be lost on amino-acylation. It is curious that polypeptidyl-tRNA is found to sediment more slowly in turn than aminoacyl-tRNA (Kuriki and Kaji, *J. Mol. Biol.*, 25, 407; 1967). When the polypeptide chain is removed from such a species, the resulting tRNA will not accept its amino-acid, and is perhaps in

the "inactive" conformation, described by Fresco and others.

## How Red Cells Lose Nuclei

from our Correspondent in Cell Biology

At long last some convincing electron micrographs have been obtained of nuclear expulsion during the final stages of erythrocyte maturation in mammals (Skutelsky and Danon, *J. Cell Biol.*, **33**, 625; 1967). Mature erythrocytes in circulating mammalian blood have no nuclei. The developing immature erythroblasts are nucleate cells. Two rival theories were proposed to explain the loss of the nucleus at late stages of maturation. One, primarily based on observations of primitive erythrocytic cell lines and some pathological conditions, was that the nucleus breaks down *in situ*, by karyolysis. The other, supported by Bessis and Bricka's microcinematography (1952), was that the nucleus is normally expelled from the cell. The supporters of the karyolytic theory objected that free nuclei are rarely seen in normal erythropoietic tissues.

Several electron microscopic studies failed to yield conclusive evidence for expulsion. Authors have often made vague statements that evidence for nuclear expulsion and/or karyolysis has been found, but have failed to include the vital micrographs in their articles. Part of the difficulty apparently arises from lack of suitable tissue to study. In normal erythropoietic tissue the erythroblasts are scattered among other cell types, which means that the chance of identifying extruded nuclei in thin sections is remote. Moreover, as the work of Bessis and Bricka shows, expulsion is rapid so that it is difficult to catch a nucleus halfway out.

Skutelsky and Danon have overcome these problems by inducing pure clones of erythropoietic cells in mice spleen by injecting syngeneic bone marrow into X-ray irradiated mice. In such clones cells at all the stages of maturation occur close together, so that the final stages involving loss of nuclei can readily be examined. As the micrographs show, nuclear expulsion does occur and the process closely resembles cell cleavage following mitosis. Skutelsky and Danon have found no evidence at all of karyolysis in the 20 clones examined.

Nearly mature erythroblasts develop cytoplasmic processes resembling pseudopods and the nucleus moves into one of these, often being deformed as it passes through the narrow neck. Within a process, the nucleus rounds up again and is surrounded by a very narrow rim of cytoplasm. The plasma membrane begins to constrict about the neck of the process containing the nucleus, leaving it attached to the main body of the cell by a very narrow bridge of cytoplasm. Mitochondria aggregate in the main cell body in the region of the constriction, and presumably provide energy for any contractile process involved in constriction and for the synthesis of new plasma membrane. Vacuoles then appear in the bridge region and effect the complete separation of the nucleus from the young reticulocyte. The nuclei released are soon engulfed by macrophage, so that free nuclei are rarely seen in erythropoietic tissues.

Three questions are raised by these observations. First, what is it that triggers the whole process and brings about nuclear expulsion rather than a cell division? Secondly, what are the properties of the plasma membrane surrounding the expelled nucleus that make it readily recognizable by the macrophage?

Thirdly, can Skutelsky and Danon's observations be generalized to definitive cell line erythroblasts in all mammalian erythropoietic tissue? The answer to the last question is probably affirmative, for it is most unlikely that the method used to induce pure clones of erythroblasts would completely alter the way in which the cells lose their nuclei, and there was no indication of karyolysis.

## Cancer Research

from a Correspondent

THE forty-fourth annual report of the British Empire Cancer Campaign, published this week, includes as in previous years reports of work in a wide variety of disciplines and, even though in 1966 the Campaign collected the record sum of £2 million, the danger that the money will be spread too thinly over a broad front of attack is unlikely to recede.

Some of the more basic projects described in the report for 1966 are concerned with the problems of growth regulation and control. According to P. N. Campbell and E. Lowe (Courtauld Institute), the higher rate of synthesis of protein in regenerating liver is not related to the availability of messenger RNA nor to any factor associated with the polyosomes, but rather to the presence of an inhibitor in the membrane of the endoplasmic reticulum. Professor J. A. V. Butler and his colleagues at the Institute of Cancer Research, on the other hand, are concentrating on the physical and chemical properties of histones because these appear to be involved in the switching on and off of genetic information. G. V. Sherbert, at the same institute, reports that the histone fraction from calf thymus produces apparently specific malformations in early chick embryos. From a study of the control of the renewal of cells in mouse lung, Simnett and Heppleston (Newcastle upon Tyne) conclude that cell division in alveolar tissue is probably regulated by a mitotic inhibitor which persists in tissue culture preparations of lung. The higher mitotic index seen in cultures of newborn lung tissue is associated with the absence of this inhibitor, though systemic stimulatory factors, possibly hormones, may also be involved. Several previously reported experiments have suggested that thymectomy enhances response to chemical carcinogens. Against this background, it is surprising to find the report by A. Flaks (Leeds) that the injection of neonatal thymus tissue into mice increased their response to a carcinogen injected during the neonatal period. But in its time the thymus, like man himself, plays many parts, and it is at present difficult to see the pattern of their interrelationships. According to Koller and his colleagues (Institute of Cancer Research) although thymic cells may restore immune competence after thymectomy, they are not themselves capable of elaborating antibody; but attempts to restore immune competence in thymectomized mice by extracts of calf thymus have so far yielded negative results. A. Glucksmann and C. P. Cherry (Strangeways Laboratories, Cambridge) have made a study of the somewhat neglected epithelial cell components of the thymus. Oestrogens promote the proliferation and secretory activity of these cells and testosterone elicit the opposite response. It is suggested that these effects may be related to the differences in response to chemical carcinogens of the salivary glands and of the genital

tract in castrated female rats treated with the two types of hormone.

According to J. T. Lett and P. Alexander (Institute of Cancer Research), the molecular weight of DNA in mammalian cells may be greater than  $10^{10}$  and possibly be equal to that of a whole chromosome which is of the order of  $10^{11}$ . According to D. Petrovic and A. H. W. Nias (Christie Hospital and Holt Radium Institute), DNA damage induced in HeLa cells by radiation may be repaired more easily in the presence of suitable quantities of deoxyribonucleosides. In *Micrococcus radiodurans* single-strand DNA breaks seem to be repaired in more than one stage, because studies of molecular weights indicate restitution of more than half the breaks within 5 min while the remainder mend more slowly during the next phase of DNA synthesis.

A claim to have transformed rat embryo lung cells *in vitro* by exposing them to urethane (S. Rasheed, Mount Vernon Hospital) will certainly stimulate further investigations because its confirmation would suggest that the agent acts directly as a carcinogen and not by way of metabolite. Organ culture studies which I. Lasnitzki has carried out at the Strangeways Laboratories, Cambridge, have indicated that the human foetal lung is more sensitive to the effects of tobacco smoke condensate than the hamster foetal lung.

The influence of age on susceptibility to carcinogens is a matter of perennial interest. Lasnitzki has found that, under conditions of organ culture, explants from old and young rat prostate glands respond differently to different sex hormones. It is therefore possible that intrinsic changes in the prostate and changes in hormonal status with age are both of importance in the development of cancer in this organ.

The results of a study at St. Mark's Hospital undertaken by Morson *et al.* suggest that one in thirty patients who survive cancer of the large bowel develop a second similar cancer. This higher susceptibility to a second tumour may not apply, however, to all forms of the disease. Certainly the presence of adenomata at the time of removal of the first cancer implies an increased risk. One of the problems peculiar to the less common types of cancer is that few people see enough cases to learn by them. A special study of carcinomata of the nasopharynx (I. W. F. Hanham, Westminster Hospital) has revealed that the commonest presenting physical sign is enlargement of isolated lymphatic glands in the neck. W. T. Smith (Birmingham) has observed a range of associations between cerebral, cerebellar, brain stem, spinal and peripheral nerve lesions, and idiopathic steatorrhoea. He suggests that the syndrome may have aetiological factors in common with carcinomatous neuropathy. It is hoped that by co-operation between thoracic surgeons at the London teaching hospitals light will be thrown on the relation between thymic tumours and certain neurological and immunological syndromes associated with cancer.

Other reports are concerned with environmental chemical carcinogens, the mechanism of chemical carcinogenesis, cancer viruses, cancer epidemiology and prevention, new methods for the early diagnosis and the exact localization of tumours, and with all forms of therapy. All in all, 1966 was a year of numerous tactical gains without any obvious advance of strategic importance.

## Parliament in Britain

### Reactors

DR J. BRAY, Joint Parliamentary Secretary at the Ministry of Technology, said that no current study was being made of the use of nuclear reactors to provide process steam for industrial and district heating purposes, but the UKAEA was keeping the matter under review in consultation with the Ministry of Public Building and Works. Before seeking authorization for constructing the sodium cooled prototype fast reactor, the AEA had assessed the relative merits of fast reactors using other coolants including gas and steam. It concluded that use of sodium coolers offered the best prospect for early commercial exploitation for fast reactors, but evaluation of the possibility of other coolants would continue in the light of developments.

### Breath Testing

LORD STONHAM, joint parliamentary under-secretary of state at the Home Office, defended breath testing devices in the House of Lords. They were not, he said, precise and accurate instruments, and were only to be used for preliminary tests. In tests, eight false positive results had been obtained, all at alcohol contents of less than 80 mg/ml. Despite this, Lord Stonham did not believe that the instruments were significantly less accurate in the lower ranges. (Answer, June 29.)

### Select Committee

AT its final meeting on the study of the British nuclear power programme, the Select Committee on Science and Technology interviewed Mr Duncan Burn, whose criticisms of British developments were published recently by the Institute of Economic Affairs. (*The Political Economy of Nuclear Energy*, 21s. See *Nature*, **214**, 547; 1967). Mr Burn reiterated most of the arguments from his book, and made some suggestions for the improvement of the nuclear industry in Britain.

The CEBG, he suggested, should be re-organized into three separate units, in order to introduce a competitive element into tendering, an idea which prompted some critical questioning from the members of the committee. The UKAEA, Mr Burn claimed, had spent more on construction than on research and development, the exact reverse of the situation in the United States. Britain should try to come nearer to the American pattern, he suggested, and one way in which this could be done would be by converting the AEA to a body more like the AEC. Some parts of the AEA should be transferred to the cons<sup>ortia</sup>, which should themselves be encouraged to seek international links.

Despite his unenthusiastic assessment of the AGR, Mr Burn said that it should continue to be developed, possibly on a wider front than hitherto. He had some more hopeful things to say about another type of reactor, the thorium high temperature reactor (*Nature*, **214**, 1177; 1967). Judging by the committee's reaction, few if any of Mr Burn's recommendations can be expected to find their way into the report when it finally emerges. Whatever the merits of his case, it would undoubtedly have been put across rather better if he had protested rather less. The committee, it is thought, may issue an interim report before its final report is published later in the year.

# Projects for Schools

by

NIGEL HAWKES

Science teachers in British schools are increasingly turning to project work as a substitute for, or as an addition to, conventional practical work. Whatever the educational benefits may be, reports of projects make for good school magazines.

IN a great many British schools it has now become fashionable for experimental work to take the form of project work. Instead of—or as well as—the routine verification in the school laboratory of the supposed laws of science, schoolboys (and schoolgirls) are increasingly being allowed and even encouraged to substitute project work in which the object is to solve quite difficult practical problems. One argument in favour of this is that project work is educationally preferable, partly because it is supposed to bring “creativity” into scientific work and partly because projects present young people with more challenging problems. The fashionable work is “open-ended”.

A number of schools have recently won reputations for themselves by the high standard of their projects, and the movement away from conventional practical work has been lent extra force by a programme designed by the Schools Council for encouraging the use of projects in secondary schools. At least one of the public examinations boards gives credit for project work in some science subjects. But the traditions of school projects go further back than that, and have derived much from the field work of the biologists and geologists, for example. Evidence of how far this type of teaching has spread through the schools is supplied by the project magazines which some schools produce. A number of these have been collected in *Nature* office.

The first impression is that the project magazines tend to be excessively biological, possibly because many of the magazines derive from the school natural history society. Oundle School Natural History Society, for example, produced a report no less than 107 pages long in 1965, which included routine reports of the societies as well as A-level project work. Project work included physiological studies of the melanic forms of the peppered moth, which can be found in the Oundle area. 180 larvae were amassed, and experiments showed some intriguing results—the larvae divide into two types, one green and the other brown. By change of weight measurements, the boys determined that the two types are physiologically as well as morphologically different. The larvae were preserved by members of the school during the summer holidays, and the following year the first adults emerged. Interestingly, the first 17 to emerge were females, an occurrence with a probability of less than 0.01. The boys concluded that there is a distinction between the times of emergence of the sexes of the species under investigation.

Although the Repton school magazine *Biogenesis* is produced by the school Field Club, it does include some physical science. One boy has extracted the tar from cigarettes using a simple smoking machine which drew smoke through a series of condensers. According to his results, French cigarettes produce significantly more tar than English cigarettes. Even when filtered, French cigarettes were worse, but wisely no conclusions were drawn from this. Another boy studied the oxygen consumption of mice kept at different temperatures. Mice were put in a sealed tube to which oxygen was fed under the control of a meter which could also be used for measuring the oxygen consumption in arbitrary units. The air breathed out by the mice was re-circulated, after the carbon dioxide

had been absorbed in soda-lime. Oxygen consumption reached a minimum at 34° C and a maximum at 25° C. Below 25° C, oxygen consumption unexpectedly fell, and future work was intended to show the reason for this. The report hints, though, that experimental technique could have had something to do with it: “It may be that the huddling together of the five mice used for the experiment diminished the need for shivering.”

Eton College produces a glossy magazine called *Atom* which includes general articles as well as some excellent project work. The 1964 issue contains a description of the Eton by-pass, then being built, and this work was followed up in 1965 by a traffic survey in Eton with a Sykes counter, which consists of a rubber tube stretched across the road. Results are plotted as daily flow patterns which show peaks at 8 a.m. and 6 p.m. on weekdays. The weekly graph shows increasing peaks as the week progresses, so that Friday evening, with a flow of 2,000 vehicles per hour, is the very worst time of all to drive through Eton. These results will be particularly interesting if they are followed up by a comparison of the traffic flows before and after the opening of the by-pass.

The 1965 issue also gives details of the building of a land yacht, in order to prove that a wind-driven vehicle can travel, unaided, faster than the wind. Results, the report records, ranged from promising to spectacular, but the aim of the experiment was achieved, and speeds of up to 20 m.p.h. were reached. The best experiment of all, though, is a study of flow patterns around aerofoil sections. The apparatus consists of a trolley arranged to run in a straight line on rails above a water filled tank. The shapes to be studied are suspended from the trolley so that they dip into the water. Mounted on the trolley is a camera fitted with a shutter in the form of a rotating Maltese cross which intermittently interrupts the light falling on the camera lens. The experiment is carried out in the dark. Several small silver paper balls are carefully placed on the surface of the water in a straight line at right angles to the direction of movement of the trolley. The motor is started, the balls illuminated, and the trolley pushed at a steady speed along the rails so

Fig. 1. Smooth flow around an aerofoil section, photographed by H. E. Aubrey-Fletcher at Eton College. The velocity of the flow, given by the lengths of the dashes, is greater above the wing than below it.

Fig. 2. Turbulent flow around the wing at stalling incidence.

that the aerofoil section passes through the line of balls. The action of the shutter makes each ball appear as a dotted line following the lines of flow around the aerofoil section. Some remarkably good pictures were produced, one in particular showing the disturbed flow occurring at stalling incidence (Figs. 1 and 2).

Not all schools, perhaps, would wish to spend as much on their project magazines as Eton (although the cost does seem to be offset by some advertisements). The ideal lay-out is achieved by *Enquiry*, the magazine of the Harrow County School for Boys. This magazine, printed quarto size by a less expensive printing process, carries several pages of advertisements and a really excellent series of project reports. Three boys studied the common

mole, which is difficult, because moles are rarely seen; the technique was to trap moles alive, ring them, and release them some distance from the trap. The frequency with which the ringed moles were once again trapped showed a strong homing instinct but little capacity for learning. One was caught no less than five times. Dissection of several moles which died—evidently of fright—confirmed that moles feed on earthworms, insect larvae and imagos and a small amount of plant debris.

Three chemists at the same school carried out a survey of the solubility of lead chloride in dilute hydrochloric acid, and the physics section includes a design for a private automatic telephone exchange, an explanation of how a transistorized electronic organ works, and a description of an amateur radio station built by one of the sixth formers. In addition, *Enquiry* includes several village surveys, which seek to relate village size, shape and structure to its geography, and to determine the reasons for its development. These surveys seem to reflect the increasing interest in social science among sixth formers; if the magazine can be criticized, it is for including rather few directly experimental projects.

The Department of Education and Science itself produces a magazine called *Project*, which appears about three times a year. This is intended to stimulate interest in the schools in engineering and the applied sciences, and the latest issue has articles about North Sea gas, automated factories, computer design, medical engineering, tidal power in France, and rotary piston engines, among others. For interest, lay-out and readability, *Project* puts many more senior British technical journals to shame. Ironically, however, it contains no projects by schoolchildren.

## The Flow Behaviour of Blood in the Circulation

by  
R. L. WHITMORE

University of Nottingham\*

The effective viscosity of blood in the circulation can vary from infinity down to about 1.3 centipoise. However, the minimum value is not reached in the largest or smallest blood vessels.

As our knowledge of the cardio-vascular system increases it becomes increasingly obvious that the flow properties of blood are sometimes significantly different from those of a simple fluid, such as water or oil, which possess a constant viscosity at all rates of flow and in vessels of all diameters. The problems are to identify the parts of the circulation where divergence from simple fluid behaviour is likely to be appreciable, the reasons for it, the magnitude of any anomaly and the physiological conditions under which it is likely to be most marked. Some of these questions are discussed and analysed here.

### Rheology of Blood

Many measurements of the flow properties of blood in bulk have been made in the past<sup>1</sup>, but it is only in the past few years that it has been possible to codify them with much precision<sup>2,3</sup>. The various parameters are often reduced to a single one—the apparent viscosity—which may be defined as the tangential force which must be applied to unit area of a plane surface situated unit distance from a similar surface immersed in the liquid under test in order to produce a velocity difference of unity (Fig. 1). For a simple liquid it has a constant value; if the force is doubled, the rate of movement is doubled, but in the case of blood a doubling of the force usually more than doubles the resulting velocity. A statistical analysis of viscosity measurements on human

blood (as reported by eight different workers<sup>4-11</sup>) produces a mean apparent viscosity curve and 95 per cent probability limits of the type shown in Fig. 2. Here the shear rate (which is equal to the velocity difference between the surfaces in Fig. 1) is plotted against the apparent viscosity and it will be observed that the velocity effect becomes important at rates of shear which are less than about 50 sec<sup>-1</sup>. Reported results show<sup>1</sup> that blood also exhibits a small yield stress, which represents the tangential force which must be applied to the plane surface of unit area immersed in the liquid in order to initiate flow. This behaviour identifies blood as a Bingham plastic from the rheological point of view; it differs from that of a simple liquid where a tangential force, however small, will always produce continuous movement. The yield stress probably stems from the small attractive force which normally exists between the red cells<sup>1</sup>, and the inherent flexibility of the cells additionally contributes to the inconstant viscosity characteristics shown in Fig. 2 (ref. 12). Illness, disease or shock can seriously alter the rheology of blood, but such abnormal conditions will not be considered here, where attention will be focused on the flow of blood in vessels under normal physiological conditions.

**Large vessels.** When a fluid moves down a tube the rate at which it is sheared depends on its radial position. There is a velocity profile across the tube with a maximum value on the axis and a minimum (usually assumed to

\* Present address: University of Queensland, Brisbane, Australia.

be zero) at the wall; for a simple fluid flowing smoothly down a tube the profile is parabolic and the resistance to flow is proportional to the mean velocity. The rate of shear is a maximum at the wall and a minimum on the tube axis. In the case of blood in which the apparent viscosity depends on the rate of shear, we must calculate the total resistance to flow by summing the shearing forces across the whole cross-section of the tube, and must expect the result to depend in a fairly complicated way on the mean velocity of flow because this will control the rate of shear at any point.

The rate of shear of blood at the wall of various blood vessels in dogs and humans has been estimated on a few occasions and the data are summarized in Table 1. We can also calculate a mean value, assuming that the velocity profile is parabolic (Table 1) and in both cases the rates of shear are so large that the apparent viscosity of the blood is very near to its minimum, asymptotic value (Fig. 2). We could, in these cases, treat blood as a simple liquid of constant viscosity and introduce very little error by choosing a value which lay within the range where 95 per cent of the measured values were found to be. These limits are 1.7–4.0 centipoise (Fig. 2). If the flow were pulsatile, as in the arterial system, the rise in apparent viscosity at instants when the velocity was small would raise the flow resistance above the anticipated value but, on the whole, the assumption that the blood behaved as a simple liquid with a viscosity of about 3.0 centipoise (that is, about three times that of water) would give a good approximation to the truth.

Table 1. RATES OF SHEAR IN THE CIRCULATION<sup>1,12-18</sup>

Structure	Man		Dog	
	At the wall sec <sup>-1</sup>	Mean* sec <sup>-1</sup>	At the wall sec <sup>-1</sup>	Mean* sec <sup>-1</sup>
Ascending aorta	190†	130		
Descending aorta	120	80	400	270
Large arteries	700	470	600	400
Capillaries	800	530	700	450
Large veins	200	130	50	35
Venae cavae	60	40	200	140

\* Assuming parabolic velocity profile.

† At peak flow velocity.

The quantity flowing down the vessel in unit time, assuming it to be cylindrical, is then given by the well-known Poiseuille equation

$$Q = \frac{P\pi R^4}{8\eta l} \quad (1)$$

where  $P$  is the pressure gradient down the tube,  $R$  is the radius of the tube,  $l$  is the length and  $\eta$  is the viscosity of the blood, which equals 0.028 poise.

For greater precision at low flow velocities an equation proposed and tested by Merrill *et al.*<sup>19</sup> should be used

$$Q = \frac{\pi R^3}{4K_c^2} \left[ \frac{(PR)^{\frac{1}{2}}}{(2l)} - \tau_y^{\frac{1}{2}} \right]^2 \quad (2)$$

where  $\tau_y$  is the yield stress of the blood (assume 0.05 dyne/cm<sup>2</sup>), and  $K_c$  is the flow parameter of blood (assume

Fig. 1. Tangential force on a unit cube of liquid.

Fig. 2. Variation of apparent viscosity of blood with rate of shear.

0.168 dyne<sup>1/2</sup>sec<sup>1/2</sup>/cm). At high flow velocities equations (1) and (2) give the same result and the importance of the complex flow properties of blood at low flow rates can best be shown by an example. If it were assumed to be a simple liquid with a viscosity of 2.8 centipoise, the mean velocity of flow in a tube 0.2 mm in diameter under a pressure gradient of 0.25 cm of water/cm length of tube would be approximately 1 mm/sec (from equation (1)) and the mean rate of shear across the tube about 30 sec<sup>-1</sup>. If, however, a yield stress of 0.05 dyne/cm<sup>2</sup> and a flow parameter of 0.168 dyne<sup>1/2</sup>sec<sup>1/2</sup>/cm were assumed, the quantity flowing down the tube with the same pressure gradient would be reduced by about a third (from equation (2)).

**Intermediate-sized vessels.** When the diameter of the vessel down which the blood is moving becomes comparable with the diameter of the red cells, it is no longer realistic to represent the blood as a homogeneous fluid. In the case of human blood this condition becomes really noticeable when the vessels are less than 100 or 150  $\mu$  in diameter. The wall of the vessel represents a discontinuity so far as the suspended red cells are concerned because they are unable to penetrate it, and the positions which they can take up in its vicinity are thus restricted. This leads to a change in the nature of the physical interactions between the cells adjacent to the wall. Moreover, the cells which would have flowed down the vessel in positions from which they are now excluded by the wall travel nearer the axis and thus at a higher velocity than anticipated. This leads to a fall in the mean haematocrit in the vessel and a reduction in the resistance to flow<sup>20</sup>. The latter is usually interpreted as a smaller effective viscosity\*. It may at first seem strange that the haematocrit in a narrow vessel can be less than in the larger diameter feeding or collecting vessels, but if it is imagined that some of the red cells, instead of being radially displaced, travel along the narrow vessel on a conveyor belt which moves slightly faster than the plasma with which they entered, then the number present in the vessel at any instant will be less than if the conveyor were absent. The higher the proportion of red cells travelling on the conveyor the lower the mean haematocrit.

As the vessel becomes smaller in diameter the proportion of displaced red cells increases, and the haematocrit (and thus the effective viscosity) falls. This effect was

\* The effective viscosity is defined here as the viscosity of a simple liquid which would give the same volume flow rate as the blood in a vessel of the same dimensions with the same pressure gradient.

Fig. 3. Shearing core flow.

first studied systematically by Fahraeus and Lindquist<sup>21</sup> after whom it is named. Although there are considerable discrepancies in reported data the results of many experiments made in glass tubes of different sizes indicate that the actual haematocrit in the tube can be estimated fairly well by assuming that the cells behave as though they were concentrated in a core which reaches within about  $4\mu$  of the wall (in the case of human blood), the surrounding annulus consisting solely of plasma (Fig. 3). It should not be assumed that there is, in fact, a continuous annulus of plasma at the wall, and visual evidence that one exists at normal haematocrits is by no means conclusive<sup>4,5</sup>, but the model is convenient for calculation purposes.

The blood in the core is assumed to shear in a similar manner to a simple fluid so that the flow is categorized as "shearing core"<sup>1</sup>, the cells in general tending to orient themselves with their faces parallel to planes passing through the tube axis<sup>22</sup>. This orientation has a profound influence on the light transmission and reflexion characteristics of the blood<sup>1</sup>, and leads to the well known bright streak often seen down the axes of vessels conveying blood<sup>23</sup> and the flashing effect when the direction of flow is reversed. If it is assumed that the plasma behaves as a simple liquid, then the mean haematocrit in the tube is given by<sup>24</sup>

$$\bar{H} = H_f \left\{ \left( \frac{R-4}{R} \right)^2 + \frac{\left[ 1 - \left( \frac{R-4}{R} \right)^2 \right]^2}{2 \left[ 1 - \left( \frac{R-4}{R} \right)^2 \right] + \left( \frac{R-4}{R} \right)^2 \frac{1}{\eta_{rc}}} \right\} \quad (3)$$

where  $H_f$  is the haematocrit in the feed and  $\eta_{rc}$  is the viscosity of the blood in the core relative to that of the plasma.  $\eta_{rc}$  is found by first determining the core haematocrit,  $H_c$ , from

$$H_c = \bar{H} \left( \frac{R}{R-4} \right)^2 \approx H_f \left( \frac{R}{R-4} \right)^2 \quad (4)$$

The relative viscosity of blood at the haematocrit ruling in the core,  $\eta_{rc}$ , can then be obtained experimentally. Alternatively, existing results can be used to obtain a suitable value.

We have already seen, however, that the viscosity of blood depends on the rate of shear, and equation (3) is only true on the assumption that the core, when in movement, behaves as a simple fluid. Thus it can only be used with confidence when the flow rate is large enough for the rate of shear to which the majority of the blood is exposed to be well in excess of  $50 \text{ sec}^{-1}$ . This is probably true in most of the circulation (Table 1). A second complication is that cells may migrate further from the tube walls as the flow rate is raised, leading to an enlarged fall in the haematocrit and effective viscosity. There must at present be some uncertainty regarding the relative importance of these two effects in any particular case<sup>25</sup>, but at normal haematocrits and physiological flow rates

Fig. 4. Variation of effective viscosity of blood with vessel diameter.

the assumptions of the asymptotic value for the viscosity of the blood and an effective annulus width of about  $4\mu$  are not unreasonable. The effective viscosity of the blood, as given by the flow resistance experienced in the tube,  $\eta_{\text{eff}}$ , is then

$$\eta_{\text{eff}} = \frac{\eta_p}{1 - \left( \frac{R-4}{R} \right)^4 \left( 1 - \frac{1}{rc} \right)} \quad (5)$$

where  $\eta_p$  is the viscosity of the plasma.

If the viscosity of the plasma is taken as 1.2 centipoise the relationship between vessel diameter and effective viscosity is then as shown in Fig. 4. When the flow is very slow the yield stress might forbid the blood in the core to shear. This would raise the effective viscosity, and the limiting case—when the core moves as a solid plug—is also shown in Fig. 4.

**Small vessels.** The shearing core model of flow is satisfactory until the diameter of the cells approaches the diameter of the vessel. This corresponds to conditions in the microcirculation, and the concept of the blood shearing in a manner similar to that of a simple liquid becomes unrealistic. The corpuscular nature of blood must be taken into consideration. Observations made *in vivo* suggest that the red cells tend to follow each other axially in single file down narrow vessels with their discoidal surfaces roughly perpendicular to the axis of the vessel but deforming<sup>26</sup> into teardrop<sup>27</sup>, parabolic<sup>28</sup> or bullet<sup>29</sup> shapes and leaving a layer of plasma at the wall. This pattern can be idealized into an axial train containing red cells and some plasma, surrounded by an annulus of plasma in which the shearing predominantly takes place (Fig. 5) (refs. 1 and 22). If the train of cells and plasma is assumed to travel as a single cylindrical unit possessing an infinite viscosity, the mean haematocrit  $\bar{H}$  can be

Fig. 5. Axial train flow.

obtained by putting  $\eta_{rc} = \infty$  and  $R - 4 = \text{radius of the train, } R_T$ , in equations (3), (4) and (5) (ref. 22).

Thus

$$H = \frac{H_f}{2} \left[ 1 + \left( \frac{R_T}{R} \right)^2 \right] \quad (6)$$

and the effective viscosity

$$\eta_{\text{eff}} = \frac{\eta_p}{1 - \left( \frac{R_T}{R} \right)^4} \quad (7)$$

This simple axial train model ignores the influence of secondary, or bolus, flow which may develop in the gaps between the cells, but the change in flow resistance stemming from this effect is probably very small. It is also difficult to predict the exact range of vessel diameters over which the model should be applicable. When the vessel is some three or four cell diameters in width, the shearing core model is probably inappropriate, but it is also unlikely that the cells move in single file as required by the axial core model. Taking the diameter of a red cell as  $8\mu$  it can easily be shown from equation (6) that if the cells were compacted into a continuous core of undeformed face-to-face cells, and the vessel diameter were twice the core diameter, then the feed haematocrit would be 40 per cent. In vessels of larger diameter there would be no room in a single, concentric core for all the cells to take up a face-to-face position and some kind of shearing core flow would have to result. As the cells are oriented with the faces predominantly normal to the vessel axis when in axial core flow, but predominantly parallel to the axis in shearing core flow, the cells would probably take up changing, uncertain orientations in this intermediate region giving the "turbulent" flow pattern sometimes reported in the literature<sup>1,9,26</sup>.

In vessels smaller than  $16\mu$  in diameter, axial core flow should predominate and the minimum haematocrit and effective viscosity will be obtained when the cells form a continuous, plasma free, face-to-face axial core. The tendency for the cells to deform to form a single strand on the axis and to displace plasma from the core should increase with the velocity (Fig. 5) until constant minimum values of haematocrit and effective viscosity are reached when the core is made up entirely of red cells. The range of diameters giving these minima should therefore increase as the flow velocity is increased. For a feed haematocrit of 40 per cent the limiting condition corresponds to the core possessing a diameter of one half of that of the vessel, the mean haematocrit in the vessel then being 25 per cent and the effective viscosity approximately 1.3 centipoise (Fig. 4).

When the vessel becomes smaller in diameter than the diameter of the cells, there is a possibility that the cells move as plugs down the vessel. In this case  $R_T = R$  and reference to equations (6) and (7) shows that the tube haematocrit then equals the feed haematocrit and the effective viscosity tends to infinity. This critical condition is probably never reached in normal health, however, a thin layer of lubricating plasma usually being observed at the wall as soon as movement of the red cells commences.

### Minimum Flow Resistance

It has been mentioned that the haematocrit in a vessel down which blood is flowing can only be expected to equal that in the feed reservoir if the vessel is many times greater in diameter than the red cell, or of about the same diameter. Between these extremes there must be a vessel diameter (or range of diameters) which gives a minimum haematocrit and also a minimum resistance to flow. In the case of human blood the diameter is probably less than  $16\mu$  and greater than  $7\mu$  (ref. 22), but the exact value cannot be specified with certainty. Both minima are influenced by the flexibility of the cells and the flow

velocity, but the asymptotic values should be 24 per cent for haematocrit and about 1.3 centipoise for effective viscosity assuming a feed haematocrit of 40 per cent and a plasma viscosity of 1.2 centipoise. The mechanism bringing about this velocity dependent resistance to flow is different from that applying in large vessels where the change occurs at a constant haematocrit which equals that in the feed. Consequently the magnitude of the variation in effective viscosity with rate of flow in small vessels is unlikely to be the same as in large vessels.

If the viscosity of blood is measured by comparing its resistance to flow down a tube with that experienced by simple liquids of known viscosity, values between about 1.3 centipoise and infinity are possible, depending on the diameter of the vessel used and the velocity of flow.

A general tendency is for the apparent viscosity of normal blood to fall with increasing rate of flow. In small vessels this trend is normally accompanied by a fall in the haematocrit but not in large vessels. Where the flow is in large vessels, the viscosity settles down to a reasonably constant value if the rate of shear to which it is exposed is predominantly greater than  $50 \text{ sec}^{-1}$ . Experiments suggest that a value of  $2.8 \pm 1.1$  centipoise is applicable in the case of human blood.

In small vessels a tendency of the haematocrit (and thus of the effective viscosity) to fall with decreasing vessel diameter is superimposed on the normal velocity dependent characteristics of blood. This trend, however, is unlikely to continue down to the smallest vessels and there should be a certain size of vessel (probably between  $7$  and  $16\mu$  in diameter<sup>1,22</sup>) in which a minimum effective viscosity of about 1.3 centipoise is reached. The precise vessel sizes in which the minimum is attained may be affected by the velocity and are crucially dependent on the flexing characteristics of the red cells. Theoretical progress in this region requires better knowledge than is at present available of the elastic properties of the cells.

I thank the Nuffield Foundation for financial assistance towards research into the dynamics of blood flow of which this paper forms part.

# Particles trapped in the Potential Well behind a Mesothermally Moving Satellite

by

V. C. LIU

Department of Aerospace Engineering,  
University of Michigan,  
Ann Arbor

The presence of a negative potential valley in the near wake of a negatively charged satellite suggests the existence of a belt filled with oscillating particles.

THE recent measurements of the ionosphere using satellites have produced some interesting but unexpected results: the plasma probe studies of electron density and temperature of the ionosphere in the wake of the Ariel I satellite showed the possible presence of low frequency plasma oscillations<sup>1</sup>. Plasma resonances found with the Alouette topside sounder satellite occur at multiples of certain characteristic frequencies of high frequency plasma oscillations<sup>2</sup>. With a disturbed tenuous ionospheric plasma, which is characteristically susceptible to numerous aspects of macro and micro-instabilities, it is not difficult to attribute these anomalous results to the general plasma instabilities in the ionosphere. This problem, however, deserves more scrutiny.

It is significant to note the consistency and persistence of the characteristic oscillation frequencies observed in the Alouette ionogram. This apparently suggests that the source and site of these plasma oscillations might be of limited extent and of long duration, possibly associated with the motion of the satellite. This article suggests the possible presence of a specific mode of plasma oscillations by particles trapped in a potential well which is associated with a rapidly moving satellite, thus throwing some light on the anomalous phenomena in the contemporary ionospheric measurements, and proposes a new concept of ionospheric measurement based on the theoretical relation between the ambient plasma parameters and the oscillation properties of the plasma particles.

From the gas dynamic point of view, the motion of a geophysical satellite in the tenuous ionosphere presents a unique plasma interaction between a negatively charged body and a fully ionized medium. The speed of the satellite is usually much larger than the thermal speed of ions [ $v_i = (2kT_i/m_i)^{1/2}$ ] and yet much smaller than that of the electrons [ $v_e = (2kT_e/m_e)^{1/2}$ ] of the ambient plasma. Consequently the gas dynamic disturbances, for example, the particle density distribution in the vicinity of the moving satellite, behave superthermally with respect to the ionic flow; sub-thermally to the electronic flow. The word mesothermal is therefore introduced here to describe the speed of the satellite. The satellite interaction problem is often characterized by the condition:  $d \ll R \ll l$  where  $R$  is the characteristic size of a satellite, for example, the radius of a spherical satellite,  $l$  is the mean free path of the ambient particles and  $d$  the Debye shielding length.

The steady state distribution of particles and potential in the frontal sheath region of a moving satellite is already well known<sup>3,4</sup>. The self-consistent solution of the corresponding problem for the near-wake behind the satellite was obtained only recently<sup>5</sup>. A notable feature of the

potential distribution in the near-wake according to the self-consistent solution is the presence of a negative-potential well in the shape of a kidney extending symmetrically across the wake. The minimum potential with an absolute value in the order  $(kT_e/e)\ln(R/d)^2$  is located at a distance of about  $2R$ , in the case of a spherical satellite with radius  $R$ , from the centre of the satellite<sup>5</sup>. This negative-potential well is populated with an electron-rich mixture of ions and electrons which results from the swifter motion of electrons to fill the wake cavity behind a rapidly moving satellite. The degree of this charge separation which determines the depth of the potential well is governed by the Poisson equation of electrostatics and the prescribed boundary conditions of the wake cavity.

So far our discussion of the problem is restricted to its steady state solution which can, at best, be considered an asymptotic solution if the system is stable. In other words, to find how the behaviour of the system changes with time, we must study the perturbations to the steady state of the system. I do not intend to discuss here the general instabilities of a non-homogeneous plasma wake. Instead, the discussion is restricted to a salient mode of plasma oscillations peculiar to the potential distribution in the wake.

It is well known in plasma physics that a potential well can act as a trap to particles of opposite charge that have energies appropriate to the potential depth of the well. By trapping we mean that the ions with appropriate energies will oscillate between the ridge and the valley of the negative-potential well. To examine the oscillation mechanism of the trapped ions, it is instructive to use a simplified one-dimensional model such that the variation of potential and the oscillation of the ions take place in the  $x$ -direction only. The model may be called a diode analogue, with the free stream, in which charged particles are "emitted" into the wake cavity, identified as its cathode; the satellite surface, where electrons are absorbed and ions neutralized, its anode. A dispersion relation for the standing waves of the ionic oscillations in the potential well can be developed using an approximation similar to the Langmuir-Tonks derivation for a homogeneous plasma. A word of justification for the use of this simplified two fluid approach is in order. It is valid provided that  $T_e \gg T_i$  which is plausible, considering that only ions of low energy are trapped in the well.

Let  $n_i = n_{i0} + n'_i(x, t)$ ,  $n_e = n_{e0} + n'_e(x, t)$  and  $\phi = \phi_0(x) + \phi'(x, t)$  denote the ion density, electron density and potential respectively; the steady state densities  $n_{i0}$  and  $n_{e0}$  may be unequal, but they are taken as their respective average values, therefore independent of space. It is

assumed that the oscillation frequency is so low that the electrons are always able to maintain the Boltzmann distribution with local instantaneous potential.

$$n'_e = n_{e0} [\exp(e\phi'/kT_e) - 1] \approx n_{e0} e\phi'/kT_e$$

assuming  $e\phi' \ll kT_e$ . From the continuity equation we obtain

$$n'_i = n_{i0}(1 - ds/dx)$$

where  $s$  denotes the instantaneous displacement of the ions with respect to their steady state position. These perturbations of the space charges must comply with the Poisson equation

$$\epsilon_0 \nabla^2 \phi' = 4\pi e n_{i0}(ds/dx) + 4\pi e^2 n_{e0} \phi'/kT_e \quad (1)$$

The ionic equation of motion can be written

$$-m_i d^2s/dt^2 = ed\phi_0/dx + ed\phi'/dx \quad (2)$$

Eliminating  $\phi'$  from equations 1 and 2 and noting that  $\epsilon_0 \nabla^2 \phi_0 = 4\pi e(n_{e0} - n_{i0})$ , we obtain an equation for  $s$  similar to that of Langmuir-Tonks.

$$\frac{d^2}{dx^2} \left( \frac{d^2s}{dt^2} + \frac{4\pi e^2 n_{i0} s}{m_i} \right) - \frac{4\pi e^2 n_{e0}}{kT_e} \frac{d^2s}{dt^2} = 0 \quad (3)$$

A dispersion relation between the oscillation frequency and the wavelength  $\lambda$  can be readily obtained from equation 3 by assuming a travelling wave

$$s = A \exp\left(i2\pi ft - i \frac{2\pi x}{\lambda}\right)$$

$$f^2 = \frac{n_{i0} e^2}{\pi m_i + (m_i/8\pi)(\lambda/d)^2} = \frac{f_i^2}{1 + (n_{e0}/n_{i0})(m_i \lambda^2 / \kappa T_e) f_i^2}$$

where the Debye shielding length  $d = (kT_e/8\pi e^2 n_{e0})^{1/2}$ ; the ion plasma frequency  $f_i = (n_{i0} e^2 / \pi m_i)^{1/2}$ . The wavelength ( $\lambda$ ) or its propagation constant ( $2\pi/\lambda$ ), is real for all frequencies less than the ion plasma frequency, the upper cutoff frequency. The fact that propagating waves are obtained from a cold-ion approximation need cause no concern. It is the rapid motion of the electrons, which rush in to negate the fields set up by the ion imbalance, that causes the ion oscillations to propagate. The actual frequencies excited by the ion oscillations must be determined by the boundary condition at the edges of the potential well. The well in question has half-width in the order of  $R$ , the satellite radius, according to the result of the self-consistent solution for a spherical satellite<sup>5</sup>. The wavelength of the oscillation of interest must be such that standing waves appropriate to the geometry of the idealized diode column are obtained; in other words, the lowest harmonic oscillation has a wavelength equal to four times the half-width of the well, namely,  $R$ . It is thus obvious from the assumption,  $d \ll R$ , that we have  $\lambda/d \gg 1$ , consequently the phase velocity  $\lambda f \approx (n_{i0}/n_{e0})^{1/2} (\kappa T_e/m_i)^{1/2}$ . Other than the factor  $(n_{i0}/n_{e0})^{1/2}$ , which is assumed constant in the present analysis, the wave appears like a sound wave. It implies that the ion oscillations propagate through the plasma in a manner quite analogous to the propagation of sound through a neutral gas of temperature  $T_e$  and particle mass  $m_i$ . (A proper account of the adiabatic compression of the gas would lead to an additional factor  $\gamma$ , the ratio of specific heats<sup>6</sup>.) It would be expected, however, if there were thermal equilibrium between the electrons and ions, that is,  $T_e = T_i$ , that the ion sound (lowest harmonic) frequency for the ionosphere at an altitude of 1,000 km for a satellite with  $R = 100$  cm is estimated to be a few kilocycles per second.

The following mechanism can be advanced to account for the excitation of these oscillations. The flux of ions from the free stream enters the region of the potential well where there is an alternating electric field. Under these conditions the ion velocity is modulated. It is anticipated that a modulated ionic flux will cause fluctuations in the depth of the potential well and thus provide the required feedback mechanism.

In view of the non-homogeneity of the plasma and the relative motions between the ions and electrons in the wake, it might be expected that available mechanisms for exciting electron oscillations in the plasma are not lacking. Again using the diode analogy, I would like to draw special attention to the finding of transient modification of plasma non-homogeneity by ion oscillations in a diode discharge in which there is a maximum concentration of plasma electron<sup>8</sup>. It was found that in the interaction between the oscillations of ions and electrons, the ion oscillation may cause the maximum and minimum electron concentrations to shift in space. The coupling found between plasma electrons and ion oscillations is also noteworthy<sup>9</sup>.

When the geomagnetic field is taken into account many more modes of oscillation, particular electromagnetic oscillations, would be possible. Particular attention should be drawn to the Larmor gyration of electrons at electronic cyclotron frequency.<sup>10</sup> Here bunching of the gyrating electrons is caused by the alternating electric field (normal to the magnetic field) which is in turn caused by the bunched electrons. Self-consistent oscillations of this kind might be expected to occur near the harmonics of the electron cyclotron frequency in a very tenuous plasma.

To sum up, I have proposed a theory which throws light on the anomalous mode of ionic oscillations in the near-wake of a satellite on the basis of potential distribution from the self-consistent theory of plasma interaction<sup>5</sup>. The estimated range of frequency appears to agree with the experimental evidence of low frequency oscillations<sup>1</sup> although more specific measurements are needed to bear out the theory. The associated electron plasma oscillation and the electronic cyclotron frequency of the electrons in the potential well should throw light on the source and site of the resonance frequencies observed in the Alouette ionogram. The belt of charged particles with specific oscillation frequencies in the near-wake of a geophysical satellite could make possible a number of ionospheric measurements. Satellite-borne experiments can be devised to detect the ionic oscillations<sup>10</sup>, and electron oscillations<sup>2</sup> as the indirect measurements of the ambient electron density and temperature. A more refined theory, which takes into account the microscopic velocity distributions of the particles and applies to particles trapped in potential wells of either charge, will be presented later. The possible presence of potential wells of alternating charges in the far-wake of a satellite at mesothermal speeds would make it necessary to generalize the present theory to include the mode coupling and damping due to microscopic velocity distributions of the particles.

This work was supported by a research grant from the US National Aeronautics and Space Administration.

# Redox Chemistry of Peroxides: Energy Surface of the Perhydroxyl Ion ( $\text{HO}_2^-$ )

by

PETER JONES  
PETER G. PERKINS

School of Chemistry,  
University of Newcastle upon Tyne

The ground state of the perhydroxyl ion has been studied theoretically by the Pople-Segal self-consistent field molecular orbital method. The results suggest that 2-electron equivalent atom transfer processes may be important in the redox chemistry of peroxides.

THE structure of the perhydroxyl ion ( $\text{HO}_2^-$ ) is not easy to study experimentally, because stable crystalline hydroperoxide salts are not formed and hydrogen peroxide solutions are unstable at high pH. The ion is, however, well suited for theoretical study and this article reports the results of calculations using the Pople-Segal self-consistent molecular orbital method<sup>1</sup>.

Many of the mechanisms proposed for reactions of hydrogen peroxide invoke the perhydroxyl ion as an important intermediate species, although the modes of reaction of this ion and, indeed, of hydrogen peroxide itself have been controversial for many years. This is exemplified by the variety of mechanisms which have been advanced in attempts to describe the catalytic decomposition of hydrogen peroxide by ferric ion and ferric complexes. One aim of our work, therefore, was to examine the changes of energy and electronic charge distribution over the ground state energy surface of  $\text{HO}_2^-$  for indications of likely modes of reaction in peroxidic oxidation-reduction processes.

The system has fourteen electrons (neglecting the oxygen  $1s^2$  core) and the ground-state wave function can therefore be represented by a single determinant. The diagonal elements of the core Hamiltonian matrix ( $H_{\mu\mu}$ ) in the order H  $1s$ ; O  $2s$ ;  $2p$ ; were 13.06, 32.38 and 15.85 eV, respectively; all off-diagonal elements ( $H_{\mu\nu}$ ) were calculated by scaling the standard bond resonance integrals ( $\beta_{\text{O}-\text{O}}^0 = 31$  eV and  $\beta_{\text{O}-\text{H}}^0 = 20$  eV) in proportion to the overlap integrals between the appropriate orbitals for each nuclear configuration. The one- and two-centre electron repulsion integrals were computed theoretically from Roothaan's expressions<sup>2</sup>. Of the fourteen electrons in the  $\text{HO}_2^-$  anion, one originates from the hydrogen atom and twelve from the oxygen atoms. The additional electron cannot be allotted to any particular atom and so

was considered initially to be "smeared out" evenly over all three centres.

A non-linear triatomic system has three degrees of freedom which, in this case, are the O-O and the two OH interatomic distances. In order to reduce the number of calculations the former was first fixed at 1.26 Å, that is, the O-O bond length in the  $[\text{O}_2^-]$  ion<sup>3</sup>. The total self-consistent electronic energies of systems in which the hydrogen atom was considered situated at a series of points in one quadrant of the molecule were calculated from the equation of Pople and Segal<sup>1</sup>.

$$E_{\text{SCF}} = \frac{1}{2} \sum_{\mu, \nu} P_{\mu\nu} (F_{\mu\nu} + H_{\mu\nu})$$

In this treatment both OH distances were allowed to vary simultaneously by expressing them in the spheroidal co-ordinations  $\lambda$  and  $\mu$  (Fig. 1a). These are defined by

$$\lambda = \frac{r_A + r_B}{R} \quad \mu = \frac{r_A - r_B}{R}$$

Thus curves of constant  $\lambda$  are ellipses with the oxygen nuclei as common foci, while curves of constant  $\mu$  are the orthogonal confocal hyperbolae (Fig. 1b). The whole problem is, of course, invariant to rotation about the O-O bond axis.

The limits of  $\lambda$  range from 1 to  $\infty$ , and for  $\mu$  they are 0 to 1 in the quadrant considered. Calculations were performed in which  $\lambda$  assumed the values 1.3, 2.0, 2.5, 3.0, 3.5 and, for each of these,  $\mu$  was varied, in the first instance, over the range 0 (0.2)1. In later work additional calculations became necessary to locate the precise position of the minimum on the energy surface. The energies of the anion at large OH internuclear separations ( $\lambda = 6$ ;  $\mu = 0.2, 0.4, 0.6, 0.8$ ) were also computed, and the case  $\lambda = 6$ ,  $\mu = 0.8$  was taken as the energy zero. In these latter cases and those in which the three atoms were colinear, it was necessary to calculate the energies by hand (*vide infra*).

All the calculations were carried out on the KDF9 computer at the University of Newcastle upon Tyne, using a fully automatic SCF programme.

**Results.** (a) *Energies of the system.* Figs. 2a and 2b are plots of  $E_{\text{SCF}}$  against  $\lambda$  for constant  $\mu$  and  $E_{\text{SCF}}$  against  $\mu$  for constant  $\lambda$ , and so illustrate the energy changes accompanying movement of the hydrogen nucleus along the co-ordinate surface in either direction. The energies of certain geometrical configurations in which the oxygen

Fig. 1.

Fig. 2. (a) Variation of  $E_{scf}$  (eV) with  $\lambda$  at constant  $\mu$ .  $\circ$ ,  $\mu=0$ ;  $\Delta$ ,  $\mu=0.2$ ;  $\square$ ,  $\mu=0.4$ ;  $\nabla$ ,  $\mu=0.6$ ;  $\bullet$ ,  $\mu=0.8$ ;  $\blacksquare$ ,  $\mu=1.0$ . (b) Variation of  $E_{scf}$  (eV) with  $\mu$  at constant  $\lambda$ .  $\circ$ ,  $\lambda=2.0$ ;  $\Delta$ ,  $\lambda=2.5$ ;  $\square$ ,  $\lambda=3.0$ ;  $\bullet$ ,  $\lambda=3.5$ .

and hydrogen nuclei lie in close proximity are too high for inclusion on the same scale; this stems from the large nuclear repulsion term in the energy equation. Finally, the lowest energy of the ion, for an O-O bond length of 1.26 Å, results when  $\angle OOH$  is  $105^\circ 18'$ , and the shortest OH bond has a length of 1.197 Å. The ionization potential of this configuration is 9.86 eV.

An interesting feature revealed by the calculations is that, although the minimum energy of the ion lies on the curve for  $\mu = 0.6$  (at  $\lambda = 2.5$ ), the curve for  $\mu = 0.8$  crosses this as  $\lambda$  increases. This means that the lowest

energy route by which a hydrogen atom can leave the ion first entails its crossing from the hyperbola  $\mu = 0.6$  to that of  $\mu = 0.8$ , and then following this hyperbolic path. The energy required to remove the hydrogen completely is  $\sim 6.5$  eV.

(b) *Electronic charge distribution.* The calculations also give the  $\sigma$  and  $\pi$  charge distributions throughout the ion. There is, in fact, no O-O  $\pi$  bonding and a lone pair of electrons resides on each oxygen atom, in an orbital of  $\pi$  symmetry. The distribution of  $\sigma$  electronic charge on the three atoms is extremely informative: (i) in the configuration of lowest energy the hydrogen atom carries an excess charge of 0.127e, the central oxygen 0.269e and the terminal one 0.604e; (ii) from the change in occupancy of the hydrogen 1s orbital, with increasing  $\lambda$  at constant  $\mu$  (Fig. 3), it can readily be seen that, independent of the value of  $\mu$ , the electronic charge on hydrogen builds up to two electrons as  $\lambda$  increases. In this limiting situation there are no off-diagonal elements in the density matrix between the hydrogen and any of the oxygen orbitals. As previously noted, the automatic calculation of the electronic energy of such structures fails, because the lowest virtual and the highest doubly occupied molecular orbitals (which contain no contribution from hydrogen 1s) are near-degenerate. No allowance was made for such a situation in the programme and these energies were therefore obtained from separate hand calculations.

We conclude that for large OH distances, the system approximates to an  $H^-$  ion and singlet molecular oxygen and should yield these initially on decomposition.

(c) *Variation of O-O bond length.* A second series of calculations was carried out to demonstrate the effect of O-O bond lengthening on the electronic charge distribution throughout the "minimum energy" ion. In this the O-O bond length was increased from 1.26 Å to 8.468 Å in steps of 0.945 Å and the self-consistent density matrix calculated for each case. The results illustrate that the excess charge on the terminal oxygen decreases regularly from 0.604e (O-O bond length 1.26 Å) to 0.055e when the two oxygens are separated by 8.468 Å. Hence at very large distances the whole of the "extra" electron resides on the OH moiety, a result which suggests that, when the O-O bond is broken, the ion will generate a neutral oxygen atom and a hydroxyl ion.

Fig. 3. Variation of H 1s orbital occupancy with  $\lambda$  at constant  $\mu$ .  $\circ$ ,  $\mu=0$ ;  $\Delta$ ,  $\mu=0.2$ ;  $\square$ ,  $\mu=0.4$ ;  $\nabla$ ,  $\mu=0.6$ ;  $\bullet$ ,  $\mu=0.8$ ;  $\blacksquare$ ,  $\mu=1.0$ .

**Reaction mechanisms.** The results of our calculations have possible implications for the mechanisms of a wide variety of peroxide reactions, for example, the types of mechanism indicated are where  $\text{HO}_2^-$  acts (i) as a two electron equivalent reducing agent by hydride ion transfer; the product oxygen molecule thereby released should be a singlet species; and (ii) as a two electron equivalent oxidizing agent by oxygen atom transfer.

(i)  $\text{HO}_2^-$  as a reducing agent. For the oxidation of hydrogen peroxide by alkaline chlorine (that is, hypochlorite) solutions, the evidence for a hydride ion transfer mechanism is compelling. Chemiluminescence accompanies the reaction, and is associated with transitions involving initially produced singlet oxygen molecules<sup>4</sup>. The transition states in these reactions may have different numbers and arrangements of protons, so that a number of contributions to the total reaction can be expected and are indeed indicated by kinetic studies of  $\text{pH}$  effect<sup>5</sup>, although the essential redox process is unchanged. These processes may, for example, be represented by

all of which involve a flow of electrons from right to left, resulting in a net two electron equivalent redox process. Reduction by way of the hydrogen peroxide molecule is readily included in these schemes by coupling proton dissociation and hydride ion transfer. Anbar<sup>6</sup> has recently shown that  $\text{NO}_2^-$  and  $\text{NO}_3^-$  are formed when hydrogen peroxide is oxidized *in situ*, by hypochlorite and a number of other oxidizing agents, in the presence of molecular nitrogen. He considers that the oxidation of nitrogen molecules involves attack by ( $^1\Delta_g$ )  $\text{O}_2$  produced by the oxidation of hydrogen peroxide.

(ii)  $\text{HO}_2^-$  as an oxidizing agent. Higginson and Marshall<sup>7</sup> classify hydrogen peroxide as a preferred two-electron equivalent oxidizing agent. The interpretation of the peroxide oxidations of a variety of inorganic and organic species as nucleophilic displacements on peroxidic oxygen by the reductant has been discussed fully by Edwards<sup>8</sup>. Tracer experiments have in several cases shown direct oxygen atom transfer, for example, the oxidation of nitrite ion by peroxyacids<sup>9</sup>. Patterns of substituent effects, both in reductants<sup>10</sup> and peroxidic oxidant<sup>11</sup>, are all consistent with the description of these processes as two electron equivalent oxidations occurring by displacement on peroxidic oxygen. Coupled proton loss, either to the solvent or, in favourable cases such as epoxidation of olefins by peroxyacids, by way of a cyclic transition state to the leaving anion, is also involved in these reactions. Alkyl and, particularly, acyl hydroperoxides are preferred to hydrogen peroxide in these oxidations because the  $\text{RO}^-$  anions are better leaving groups compared with the hydroxide ion. Although there is no direct evidence for the transfer of oxygen atoms in the case of oxidation by hydrogen peroxide and  $\text{HO}_2^-$ , our calculations suggest that these species probably conform to the behaviour pattern, already established for hydroperoxides in general.

(iii) The catalytic decomposition of hydrogen peroxide. For the present, discussion is restricted to ferric complexes as catalysts. Kremer and Stein<sup>12</sup> have suggested that  $\text{FeO}^{3+}$

is an important species in ferric ion catalysis and that it is formed by loss of  $\text{OH}^-$  from a ferric ion perhydroxyl ion complex. Wang<sup>13</sup> suggests that the high activity of the triethylenetetramine-ferric complex derives from a situation in which the O-O bond in a co-ordinated perhydroxyl ion is first stretched across two *-cis* co-ordination positions and subsequently generates co-ordinated O and  $\text{OH}^-$ . There is considerable evidence that catalase compound I contains both oxidizing equivalents of its parent hydrogen peroxide molecule (for a review see ref. 14), and Jones and Wynne-Jones<sup>15</sup> have argued that the ferric ion and catalase reactions are probably closely related mechanistically. Yonetani<sup>16</sup> has shown that cytochrome peroxidase compound II contains both oxidizing equivalents of its parent hydrogen peroxide molecule.

If the first step in catalysis is the "activation" of peroxide as a two electron equivalent oxidizing agent, the reaction sequence may then be completed by a two electron equivalent oxidation of a second hydrogen peroxide molecule or a perhydroxyl ion, for example

This has been suggested both for the ferric ion reaction<sup>17</sup> and for the catalase reaction<sup>18</sup>. This model accounts for both kinetic and deuterium isotopic effects and is readily extended to account for peroxidatic oxidations.

Doctrinaire application of exclusive one electron transfer principles is clearly inadequate for complete description of the redox chemistry of hydrogen peroxide, because two electron equivalent atom transfer processes are energetically favourable. Considering the perhydroxyl ion alone we may compare

with

Discussions of, for example, the decomposition of hydrogen peroxide catalysed by ferric ions have largely regarded one electron equivalent and two electron equivalent redox paths as mutually exclusive, whereas it would seem more pertinent to investigate the relative contributions of the two paths to the total reaction in particular cases.

Our results indicate an interesting relationship between the catalytic decomposition of hydrogen peroxide involving two electron equivalent steps and the thermal decomposition of acyl hydroperoxides (peroxyacids). In the former case "activation" of hydrogen peroxide as an oxidant by interaction with the catalyst is rate limiting. This activation, which probably involves O-O bond cleavage, yields mechanisms with rate laws showing a characteristic first-order dependence on hydrogen peroxide. In the latter cases the mutual oxidation-reduction step is rate limiting, O-O bond cleavage and oxygen release are synchronous, yielding a characteristic second-order rate law<sup>19</sup>. In accord with these ideas, very pure hydrogen peroxide is kinetically extremely stable<sup>20</sup>. A subtle feature of peroxyacid decompositions is that the electrophilic centre may not be the carboxyl carbon atom in an acyl hydroperoxide, but may be the outer peroxidic oxygen atom of the peroxyacid molecule. Both centres may contribute to the total reaction, the contributions being distinguishable by isotopic labelling<sup>19</sup>. It would be interesting to compare experiments with calculations of

the structural variation of electronic charge density in these systems.

## Identity of a Urinary "Pink Spot" in Schizophrenia and Parkinson's Disease

by

ALAN A. BOULTON

Department of Chemistry,  
University of Birmingham,  
Birmingham

The substance producing the controversial pink spot on paper chromatograms from urine obtained from patients with Parkinson's disease and some schizophrenics has been submitted to mass spectrographic, ultra-violet and infra-red analysis. The results of these studies would seem to suggest that the pink spot first found by Friedhoff and van Winkle consists of *p*-tyramine and not  $\beta$ -3,4-dimethoxyphenylethylamine as was previously thought.

CONSIDERABLE activity has followed Friedhoff and van Winkle's<sup>1</sup> finding that a substance producing a pink coloration after dipping paper chromatograms through ninhydrin and Ehrlich's reagents occurs only in extracts of the urine of schizophrenic patients. This finding has to some extent been confirmed in other laboratories<sup>2-6</sup>. Perry *et al.*<sup>7,8</sup> and Nishimura and Gjessing<sup>9</sup>, using more sophisticated techniques and patients maintained on carefully controlled diets, failed to locate this pink spot. Von Studnitz and Nymann<sup>10</sup> reported its disappearance from the urine when only glucose, citric acid and water were ingested. Largely from a study of the chromatographic behaviour of the pink spot and some of its derivatives, Friedhoff and van Winkle<sup>11</sup> identified the substance as  $\beta$ -3,4-dimethoxyphenylethylamine (DMPE). Such a finding in schizophrenia would seem to confirm the implications of earlier hypotheses. In 1952 Osmond and Smythies<sup>12</sup> and Harley-Mason<sup>13</sup> postulated an abnormal methylation of catecholamines. More recently<sup>14-16</sup> it has been shown that feeding substances capable of donating a methyl group can cause an exacerbation of schizophrenic symptoms, although normal people also become more excited under the same conditions.

Our own early attempts to locate the pink spot were not very successful. We were misled by various false positive results due to drug metabolites. In an investigation of urine from seventy-three schizophrenic patients we have found seven which show the spot described by Friedhoff. In attempts to increase the sensitivity of detection, and also allow quantitative evaluation, we tried to convert the pink spot zone on paper chromatograms to a fluorophore according to the procedure described by Bell and Somerville<sup>17</sup>. Although the addition of authentic DMPE to urine always produced a blue

fluorescence, this was never observed in any pink spot urine<sup>18,19</sup>. Similarly, Bell and Somerville<sup>20</sup>, using electrophoresis, were unable to observe any fluorescence from urines showing the pink spot. Extensive chromatographic investigations by Faurbye and Pind<sup>5,21</sup> and Williams *et al.*<sup>22</sup> failed to reveal any substance identical with DMPE. Barbeau *et al.*<sup>23,24</sup>, using Friedhoff and van Winkle's method, have recently shown that a pink spot occurs in the urine of 80 per cent of patients suffering from Parkinson's disease. We have confirmed this finding<sup>19</sup> and shown again that the substance is not DMPE, because it also fails to produce the characteristic blue fluorescence. At this stage, therefore, it is confirmed that the pink spot substance occurs in the urine of some schizophrenics and most Parkinsonian patients. It is not DMPE. An eluate from a paper chromatogram of the pink spot material was optimistically subjected to mass spectrometry; the result (Fig. 1d) was very complex and merely confirmed that DMPE was not present. To obtain more pink spot material, phenolic amines from the urine of a Parkinson patient with pink spot urine were concentrated by the procedure of Kakimoto and Armstrong<sup>25</sup>. This technique was used by Nishimura and Gjessing<sup>9</sup> and Takesada *et al.*<sup>4</sup> in their studies on pink spot excretion. According to Perry *et al.*<sup>26</sup> a 96 per cent recovery of DMPE is obtained, whereas with a chloroform extraction from alkaline urine the recovery at best is only about 50 per cent<sup>18</sup>. We were surprised to find that the recovery of pink spot was five times greater than when using chloroform. The extract was applied to the top of a dry cellulose powder (Whatman CC31) column (70 cm long, 2.1 cm diameter) and developed with butanol : acetic acid : water; 60 : 15 : 25 (v/v) (ref. 27). Substances emerging from the column between 75 and 85 ml. had *R<sub>F</sub>* values of roughly 0.55-0.70 on paper

in the same solvent system. This achieved a considerable purification as assessed by subsequent chromatography. The extract was still somewhat contaminated, but the ultra-violet absorption spectrum in 0.001 normal hydrochloric acid ( $\lambda_{\max}$  219, 273 and 280 shoulder  $m\mu$ ) was rather similar to that obtained for DMPE. In 0.001 normal sodium hydroxide, however, there was a marked change ( $\lambda_{\max}$  237 and 293  $m\mu$ ). These spectra were suggestive of a free phenolic group attached to a benzene nucleus. The mass spectrum of this extract was still somewhat confusing, but peaks corresponding to 4-hydroxyphenylethylamine (*p*-tyramine) seemed significant. The extract was finally separated on an 'Amberlite CG-50' column operated at 40° C as described by Perry and Schroeder<sup>28</sup>. The unknown substance was eluted at the *p*-tyramine position as determined by a previous separation of a synthetic mixture of pyrrolidine, DMPE and *p*-tyramine. The infra-red spectrum (potassium chloride disk) of the unknown was identical with that of the synthetic *p*-tyramine obtained from the column.

In order to confirm that *p*-tyramine was the significant pink spot in our studies, extracts were prepared from urines previously classed as positive by the Friedhoff technique. In the first case urine from a schizophrenic, containing 1.1 g of creatinine, was fractionated and concentrated. The second sample, also containing 1.1 g of creatinine, was from pooled urine obtained from four different Parkinson patients. All the fractions from the

cellulose column and the ion-exchange column were analysed by paper chromatography. Pink spots were located with ninhydrin and Ehrlich's reagents<sup>29</sup>. DMPE and *p*-tyramine were run as standards and in relatively uncontaminated extracts it is possible to distinguish between them. In both the schizophrenic and Parkinson samples the only significant (90 per cent or more as assessed visually) pink spot was *p*-tyramine and this was eluted from the ion-exchange column between 110 ml. and 130 ml. with a maximum at 118.5 ml. Many minor spots were observed, some of them pink, but apart from showing in the mass spectrometer that they did not contain DMPE they were not examined further: they may or may not be similar to those described by Perry *et al.*<sup>28</sup>. Nothing was found at the peak elution volume (95 ml.) of DMPE. The pink spot fractions had ultra-violet, infra-red and mass spectra (see Fig. 1*b*, *e* and *f*) identical with those of synthetic *p*-tyramine and in this latter case the identity of the ions producing the significant mass peaks were determined by precise mass measurement and shown to be completely consistent with the structure of *p*-tyramine. The chromatographic (butanol:acetic acid:water; 60:15:25 (v/v), and isopropanol:ammonia:water; 200:10:20 v/v) and electrophoretic (aqueous formic acid 1.56 per cent, acetic acid 2.96 per cent, pH 2.0) properties were identical and none of the fractions, including synthetic *p*-tyramine, fluoresced after treatment with glycine-formaldehyde. *m*-Tyramine, which has somewhat similar ion-exchange and mass spectral properties, was ruled out as a major contributor to the pink spot because of the difference in colour produced with diazotized *p*-nitroaniline<sup>30</sup> on paper chromatograms and because the infra-red spectrum of *m*-tyramine is very different from that of *p*-tyramine. *o*-Tyramine is excluded because it is eluted much later from the CG-50 resin<sup>28</sup>.

Analysis of each fraction from the ion-exchange column, however, by the fluorimetric procedure described by Coulson *et al.*<sup>31</sup> revealed that *m*-tyramine (elution maximum 125 ml.) was present to the extent of 10  $\mu\text{g}/1.1$  g creatinine in the schizophrenic sample and 28  $\mu\text{g}/1.1$  g creatinine in the Parkinson sample. The total amount of *p*-tyramine in the ion-exchange fractions was measured by the fluorimetric procedure described by Udenfriend<sup>32</sup> and was 1,289  $\mu\text{g}/1.1$  g creatinine in the schizophrenic and 2,211  $\mu\text{g}/1.1$  g creatinine in the case of the Parkinson specimen.

It is quite possible that the pink spot identified in these studies is different from those described by other workers, but its identity as *p*-tyramine could account for certain of their observations. Friedhoff and van Winkle, in their original report<sup>1</sup>, stated that the urine extractions must be done quickly because the unknown is readily oxidized in alkaline solution. It is difficult to see why this would be important if the unknown were DMPE. Takesada *et al.*<sup>4</sup> found the pink spot to be present in normal subjects. This is explicable because they used the resin technique which gives a much higher recovery; furthermore, *p*-tyramine is a normal constituent of urine<sup>25</sup>. Because *p*-tyramine runs a little ahead of DMPE during electrophoresis at pH 6.2 in phosphate buffer it might explain the findings of Bell and Somerville<sup>30</sup>. The chromatographic and chromogenic properties of *p*-tyramine and DMPE are sufficiently similar to explain the observations that have been reported so far.

The significance of these abnormally large amounts of urinary *p*-tyramine is not yet understood. In the case of schizophrenia the pink spot has been somewhat elusive, of low incidence and perhaps directly related to exogenous sources<sup>10,12,26</sup>; it may even turn out to be a red herring, as recently suggested by *The Lancet*<sup>33</sup>. In the case of Parkinson's disease, however, the incidence is much more significant. The low concentrations of dopamine in urine<sup>34,35</sup> and certain areas of the brain<sup>36-38</sup> are interesting and may be related to this finding. A longitudinal experiment designed to show whether the excreted

Fig. 1. Simplified monoisotopic mass spectra as obtained using the MS9 A.R.I. mass spectrometer. *a*, *b* and *c* represent DMPE, *m*-tyramine and *p*-tyramine, respectively, in the free base form. *d* is the pink spot zone eluted in 0.01 normal hydrochloric acid from a paper chromatogram. The eluate was adjusted to pH 10.5 with sodium hydroxide and shaken ( $3 \times 15$  ml.) with chloroform. The chloroform extract after drying over sodium sulphate was rotary evaporated to dryness and dissolved in 70 per cent ethanol for analysis. *e* and *f* represent schizophrenic (*e*) and Parkinson (*f*) eluates as obtained from the CG-50 column (see text). The eluates in aqueous pyridine acetic acid buffer, pH 6.32, were rotary evaporated to dryness and dissolved in 70 per cent ethanol for analysis. The small peaks at 185 and 259 in samples *e* and *f* are always seen and may represent contaminants from the resins, buffer or solvent solutions. They were shown to be unimportant by mixing a small amount of samples *e* and *f* with deuterium oxide; on subsequent analysis the *p*-tyramine fragment peaks and the molecular ion peak increased by one in all cases. The 185 and 259 peaks remained the same.

*p*-tyramine is mainly of exogenous or endogenous origin is in progress.

We thank Professor Brodie-Hughes, Professor W. Trethowan and Dr A. Maiden for samples of urine from their patients. We also thank Miss C. Felton and Miss M. Reade for their assistance in certain parts of this study, and Dr P. Smith for a gift of 1 mg of *m*-tyramine.

## Light and Dark Adaptation in the Isolated Rat Retina

by

GEORGE W. WEINSTEIN

ROBERT R. HOBSON

JOHN E. DOWLING

Wilmer Institute,  
Johns Hopkins University School of Medicine,  
Baltimore, Maryland

A living isolated retina exhibits the initial fast phase, but not the later slow phase of dark adaptation. The irreversible loss of sensitivity with adaptation to bright light in this preparation is directly related to the bleaching of rhodopsin.

A VIABLE isolated retina, because of its thinness and transparency, offers a unique opportunity for combined physiological and biochemical measurements on a piece of living nervous tissue. Sickel<sup>1,2</sup> and Ames<sup>3,4</sup> have developed methods for maintaining the isolated mammalian retina alive while it is mounted as a membrane in a chamber perfused by an enriched medium.

One problem that is particularly suitable for analysis with such a preparation is the relation of visual pigments to visual sensitivity. This problem is difficult to approach because in man, in which it is easy to determine visual sensitivity, it is difficult to measure visual pigments. In animals, conversely, visual pigments are readily measured by extraction, but visual sensitivity is difficult to determine.

Some progress, however, has recently been made with this problem in both man and animals by indirect methods. Rushton has developed an elegant technique for measuring the amount of visual pigment in the intact human eye, and he has been able to compare the content of visual pigment in both rods and cones with visual sensitivity determined in parallel psychophysical experiments<sup>5-8</sup>. One of us (J. E. D.) has carried out similar experiments with rats by comparing sensitivity of the electroretinographic response with the amounts of visual pigment extracted later from the same or similarly treated animals<sup>9</sup>. Both types of experiment indicate that the loss of sensitivity during light adaptation is essentially independent of the amount of visual pigment bleached, but that dark adaptation consists of two components: an initial fast component, independent of concentrations of visual pigment, and a

later slow component, closely related to concentrations of visual pigment. The relation of the slow component of dark adaptation is between the logarithm of visual sensitivity and the concentration of visual pigment.

The isolated retinal preparation permits simultaneous measurement of visual sensitivity and concentrations of visual pigment, and thus provides a more direct test of the foregoing results. It has been known since the time of Kühne<sup>10</sup>, however, that a retina isolated from the pigment epithelium does not regenerate visual pigment. In such a preparation, therefore, one should have the added advantage of being able to separate more clearly the fast, non-photochemical components of adaptation from the photochemical components. Any bleaching of pigment should result in a permanent and stable change in the sensitivity of the preparation—similar perhaps to the stable rise of threshold observed in vitamin-A deficiency of the retina, in which there is not sufficient retinaldehyde (retinene) available to synthesize a full complement of visual pigment in the retina<sup>11,12</sup>.

We have performed the following experiments on retinæ obtained from albino rats anaesthetized with 'Nembutal', dissected out in dim red light and mounted between two pieces of tantalum wire mesh in a 'Lucite' chamber, similar to that described by Sickel<sup>1,2</sup>. The tantalum meshes support the retina and also serve as electrodes to record the electroretinogram. Perfusing fluid, kept at 30° ± 2° C and similar in composition to that used by Ames<sup>3,4</sup> (Table 1), was allowed to flow over the sandwiched retina at a rate of 2-3 ml./min. The sides of the chamber at the level of the retina had previously

been drilled out and replaced by cover glasses to provide a clear optical path through the chamber to the retina. The chamber was then mounted in the sample compartment of a Cary model 14 recording spectrophotometer. Two accessory lamps for stimulating and adapting purposes were mounted above the compartment; and lenses, mirrors and shutters were fitted in to deliver beams of focused light to the retina. The apparatus is shown schematically in Fig. 1. With this technique it is possible to record the absorbance of visual pigment in the retina, and to adapt and to measure retinal sensitivity by the electroretinogram response for a light-intensity range of 7-8 log units.

Most of the retinæ maintained in these conditions remained viable and gave good electroretinogram responses for experiments lasting 4-6 h. In preliminary experiments with another chamber, opened on one side for the insertion of a microelectrode, we recorded the spike activity of single ganglion cells for periods of several hours, and these responses also seem to be entirely normal. The electroretinograms recorded from properly maintained retinæ *in vitro* appear almost identical with those recorded from intact animals. Typical responses from a dark adapted and then partially light adapted preparation are shown in Fig. 2. From the dark adapted retina (Fig. 2, column *a*) only the vitreal-positive *b*-wave is recorded with stimuli of low intensity; stimuli of higher intensity are needed to record the vitreal-negative *a*-wave preceding the *b*-wave. With bright stimuli, large *a*-waves are

Fig. 1. Schematic arrangement of the perfusion chamber in the spectrophotometer. When mirrors ( $M_1$  and  $M_2$ ) are in down position (solid lines), adapting (left) and stimulating (right) lights are focused on the retina, which is mounted vertically in the chamber. With the mirrors in the up position (dotted lines), the monochromator beam passes through the specimen into the photocell compartment. Light intensity is controlled by neutral density filters ( $F_1$  and  $F_2$ ), and duration by camera shutters ( $SH_1$  and  $SH_2$ ). The spectrophotometer beam is condensed by lens ( $L_1$ ), the adapting and stimulating beams by lenses ( $L_2$  and  $L_3$ ). The specimen is perfused through flexible tubing leading to and from the perfusion system; leads from the tantalum grids, which support the retina, are connected to the recording amplifier.

Fig. 2. Electroretinograms from a dark adapted and partially light adapted isolated retinal preparation. (*a*) Electroretinograms from retina in the fully dark adapted state showing increasingly larger responses to brighter light stimuli, the intensity of which is given in log units above the criterion response. Vitreal-positive *b*-wave is shown as an upward deflection, vitreal-negative *a*-wave as a downward deflection. (*b*) Decrease in sensitivity produced by a weak adapting light (log  $I = 2$ ). Threshold response is not achieved until the stimulus light is about 2 log units brighter than that required to produce the criterion response in the dark adapted state. (*c*) Complete recovery of sensitivity 2 min after the weak adapting light is extinguished. (*d*) Greater loss of sensitivity with brighter adapting light on (log  $I = 4$ ). (*e*) Partial recovery of sensitivity 2 min after extinction of the bright adapting light. The criterion response is obtained with a stimulus 2 log units brighter than that required for the dark adapted retina. The responses of column *f* are identical with those of column *e*, showing no further recovery of sensitivity after an additional 10 min of dark adaptation. All records are responses to 1/50 sec flashes.

evoked from the isolated retina, and often a larger *a*-wave (relative to the size of the *b*-wave) can be evoked from the isolated retina than from the eye of an intact animal. No *c*-wave is seen in such preparations, but a *c*-wave can seldom be evoked from the intact eye of an albino rat<sup>12</sup>. With preparations which are not satisfactorily maintained, the *b*-wave selectively disappears and the *a*-wave dominates the electroretinogram response. This is readily detected; when it occurs, the preparation is abandoned.

When background light is shone on a well maintained preparation, the electroretinogram rapidly loses sensitivity and the responses are considerably reduced in amplitude (Fig. 2, columns *b* and *d*). With dim adapting lights, the sensitivity and size of the electroretinogram response quickly recover to the dark adapted condition when the background light is extinguished (Fig. 2, column *c*). With brighter background lights, however, only partial recovery is noted when the adapting light is extinguished. This partial recovery is quickly accomplished; no slow component of dark adaptation is seen in time, such as is observed from an intact eye of a rat<sup>9</sup>. In Fig. 2, columns *e* and *f*, electroretinograms were recorded 2 and 10 min after the extinction of the bright background light. No changes in sensitivity, form or size of the responses were observed during this period.

Fig. 3 shows a record of absorption curves from a viable isolated retina which was dark adapted and then light adapted with background light of various intensities. The broad absorption band of rhodopsin, with a peak at about 500 nm, is clearly seen on the record. Curves 1-6 are recordings made with the retina dark adapted, and after exposure to dim background light that did not significantly reduce the concentration of visual pigment (see legend to Fig. 3 for details). All these curves are essentially identical. Curves 7-12 are runs made after exposures to adapting lights that bleached measurable fractions of the visual pigment. After each 5 min adapting exposure, two runs were made; the first was made 4-8 min after the light adaptation period; the other 20-30 min after the adaptation. In each case the pair of curves is

essentially identical, showing that no regeneration of visual pigment occurs in the living isolated retina. Curves 13 and 14 are runs made after a complete bleach of visual pigment by 10 min of exposure to the brightest light available. Further light adaptation beyond this does not significantly change the absorption curve of the retina. The total change of absorbance from dark adapted retina to light-adapted retina was 0.23. In eight experiments, we obtained an average absorbance of rhodopsin of 0.25.

If we assume that rat rhodopsin has a molar absorbance similar to cattle rhodopsin (40,600) (ref. 14), and that the rhodopsin in the intact rat rod is oriented and has an absorbance 1.5 times that of rhodopsin in solution<sup>15</sup>, then the measured absorbance of rhodopsin in the isolated rat retina corresponds to a concentration of  $4.2 \times 10^7$  molecules of rhodopsin in each rod. Previous estimates from extracts of the rat retina suggested that there are  $3.2 \times 10^7$  molecules of rhodopsin in each rod<sup>16</sup>.

Figs. 4 and 5 present combined physiological and biochemical data from two typical experiments. The only procedural difference between the experiments was that in one experiment (Fig. 4) the adaptation period was 2 min, whereas in the other (Fig. 5) a 5 min adaptation period was used. The open circles and the heavy line indicate the loss of sensitivity or rise of threshold (increment sensitivity) while background light is on. For these experiments, sensitivity (or threshold) was determined by evaluating the intensity of light necessary to evoke a *b*-wave of 20  $\mu$ V. Except with the very dimmest background light, the loss of sensitivity is linearly proportional to the intensity of the background light (log *I*). This is the well known Weber-Fechner relation. A similar relation is seen in the intact rat, but with a slightly lower slope; *in vitro*, the slope of the line is usually about 1;

Fig. 3. Absorption curves of viable isolated retina in dark adapted and increasingly light adapted states. Curves 1 and 2 were run with retina fully dark adapted. Curve 3 was made 3 min after 5 min exposure to weak adapting light (log *I* = 1.6). Curves 4 and 5 were made 7 and 10 min respectively after exposure to a somewhat stronger adapting light (log *I* = 3.4). Curve 6 was made 17 min after extinction of that adapting light and 45 min after curve 1. Curves 1 to 6 are virtually identical, indicating that no measurable amount of photopigment has been bleached so far. Curve 7 was run 7 min after a 5 min exposure to a fairly bright adapting light (log *I* = 4.8). Curve 8, superimposed on curve 7, was run 20 min later (27 min after the adapting light was turned off.) Curves 7 and 8 are significantly lower than curves 1-6 at 500 nm, showing that a measurable amount of rhodopsin has been bleached, and that there has been no regeneration of rhodopsin in this time period. Curves 9 and 10 were made 6 and 26 min respectively after exposure to a brighter adapting light (log *I* = 5.9). The two curves are again identical, and show a change of absorbance of 0.145 from the dark adapted curves. Curves 11 and 12 were made 7 and 20 min after a 5 min exposure to the brightest adapting light (log *I* = 7.0) and indicate a further change in absorbance. Curves 13 and 14 were run after a 10 min exposure to both adapting and stimulating lamps, and show the absorption of the tissue in the fully bleached state. The net absorbance change of rhodopsin in this preparation was 0.23.

Fig. 4. The effect of 2 min of light adaptation on increment sensitivity (○), rhodopsin content (●) and dark adaptation (×; thin lines). Intensity of adapting and stimulating lights was varied by interposed neutral density filters calibrated at 500 nm. The criterion response was 20  $\mu$ V. As the retina is exposed to brighter adapting lights (abscissa), brighter stimuli (left ordinate) are required to elicit the criterion response (increment sensitivity). These measured points (○) lie on a straight line with a slope of about 1.0 (Weber-Fechner relationship). After the adapting light is extinguished, the sensitivity rapidly increases (×; thin lines). If the adapting lights are dim the recovery is complete; with bright adapting lights, recovery is incomplete and there is an irreversible loss of sensitivity. The level of recovery after a bright light adaptation correlates closely with the content of rhodopsin (●, right ordinate) left in the eye after the 2 min adaptation period. See text for details. The scale for rhodopsin was set by equating the final level of sensitivity (●) with 0 per cent rhodopsin. A 10 min time scale for dark adaptation is indicated at the top of the graph.

Fig. 5. The effect of 5 min of light adaptation on increment sensitivity, rhodopsin content, and dark adaptation. This experiment is identical to that of Fig. 4, except for the longer period of light adaptation.

in the intact animal it is closer to 0.8. We have no explanation for this slight difference.

When background light is first turned on, the increment sensitivity is established too quickly to be adequately measured by our electroretinogram techniques. This also occurs with an intact animal<sup>9</sup>. When the background light is extinguished, the sensitivity of the preparation rapidly increases (Figs. 4 and 5: crosses, thin lines). If no rhodopsin has been bleached by the adapting light, the recovery of sensitivity is complete. If some rhodopsin has been bleached, the sensitivity returns to an intermediate level and remains there. The rapid increase of sensitivity takes 1-3 min after the adapting light is extinguished. Thereafter, no further recovery is noted, whatever the level which the sensitivity reaches. In Fig. 4 sensitivity levels in some cases were determined for 40 min after extinction of the adapting light, but there was no improvement in absolute sensitivity after completion of the initial fast-recovery phase of dark adaptation. We define absolute sensitivity as the stable sensitivity which the retina reaches in the dark after a light adaptation.

Also shown in Figs. 4 and 5 are the amounts of rhodopsin remaining in the retina after exposure to the various adapting intensities. The scale for the rhodopsin was set

by equating the dark adapted sensitivity with 100 per cent rhodopsin, and equating the sensitivity measured after a complete bleach (filled square) with 0 per cent rhodopsin. The points indicating concentrations of rhodopsin are the averages of runs made immediately after the adaptation period and runs after completion of the physiological measurements (20–30 min later). Usually, no changes in absorption were noted between the two runs. Occasionally, however, the second run showed slightly less absorption, which was perhaps caused by a slight fall of the base line or by the fading of a persisting orange photoproduct. With 2 min of bleaching there was a greater tendency for second runs to be slightly lower (absorbance differences of about 0.01–0.2 at 500 nm), which perhaps favours the latter hypothesis.

In both experiments it can clearly be seen that the absolute sensitivity after the adaptation period is closely related to the amount of rhodopsin bleached. In Fig. 6 another experiment is illustrated in which only one adapting intensity was used ( $\log I = 7$ ) but for varying periods of time. Increasing the duration of the light adaptation period caused bleaching of a larger fraction of the visual pigment, and correspondingly decreased the absolute level of sensitivity. In Fig. 7 is a comparison of the relation of concentration of pigment to the absolute level of sensitivity in the three experiments illustrated. This shows a linear relation between the logarithm of the absolute sensitivity and the concentration of visual pigment. The range of sensitivity in the span from 0 to 100 per cent rhodopsin is about 6 log units. This is a somewhat greater sensitivity range than that found in the intact rat, which is about 5.2 log units<sup>9</sup>. It is, however, likely that a more complete bleach of the pigment was obtained in the present *in vitro* experiments.

These experiments with the isolated retina confirm and extend previous results and interpretations concerning the

Fig. 6. The effect of varying durations of light adaptation on dark adaptation (x; thin lines) and rhodopsin content (●). A single intensity of light ( $\log I = 7$ ) was used for 3, 30, and 300 sec adapting periods. The increment sensitivity (○) was determined during the latter two periods only, and was the same for each. Sensitivity and rhodopsin content irreversibly decreased during each period.

Fig. 7. Relation of pigment concentration to absolute sensitivity. Data from the three experiments above have been combined. This shows a linear relation between concentration of rhodopsin and the logarithm of the sensitivity.

phases of light and dark adaptation. The loss of sensitivity during light adaptation is linearly related to the logarithm of the intensity of the adapting light, for most of the adaptive range of the eye. With dim adapting lights which do not bleach a measurable fraction of the rhodopsin, the eye completely and rapidly recovers its dark adapted sensitivity when the adapting light is extinguished. If bright lights that bleach pigment are used for adaptation the recovery is not complete; instead, the sensitivity rapidly increases to an intermediate level, where it remains.

In summary, light adaptation and the fast component of dark adaptation behave independently of visual pigment levels and thus appear to be mediated by non-photochemical or neural mechanisms. On the other hand, the sensitivity which the isolated retina reaches after the fast phase of dark adaptation (absolute sensitivity) is determined by the concentration of rhodopsin remaining in the rods. Thus, this and later portions of dark adaptation are clearly photochemical. In the intact eye, rhodopsin slowly regenerates, with a corresponding recovery of log sensitivity<sup>9</sup>. *In vitro*, with no regeneration, the sensitivity remains decreased.

Donner and Reuter<sup>17</sup> have suggested from experiments on the frog that the relation during slow dark adaptation is not between the concentration of rhodopsin and log sensitivity, but rather between the logarithm of the rate of rhodopsin regeneration and log sensitivity. These authors postulate that this relation may hold also for the rat and human eye. Our experiments, however, exclude this possibility for at least the (primarily rod) retina of the rat, because in the isolated rat retina there is no regeneration, yet there is a close relation between the amount of visual pigment and absolute sensitivity. By Donner's and Reuter's formulation, we should not observe any loss of sensitivity after a bleaching adaptation in the present experiments, because we have no rate of regeneration to raise the threshold. This is clearly not the case, and our results confirm earlier work that the relation during photochemical adaptation is between the concentration of rhodopsin in the retina and the logarithm of visual sensitivity.

## Disappearance of Angiotensin from the Circulation of the Dog

by

R. L. HODGE

Measurements of the rate of disappearance of angiotensin in the blood have previously given contradictory results, with half-lives varying from a few minutes to 37 hours. It is now clear that the blood itself plays little part in the inactivation of angiotensin and that the rapid removal of angiotensin from the bloodstream occurs in the tissues through which it is carried.

RENIN, an enzyme liberated into the blood stream from the kidneys, acts on an alpha-2-globulin in plasma to produce the decapeptide angiotensin I which in turn is converted by another enzyme to the octapeptide angiotensin II (ref. 1). The physiological and pharmacological actions of the renin-angiotensin system such as increase in blood pressure, release of aldosterone<sup>2</sup>, and of catecholamines<sup>3,4</sup> reside in angiotensin II (ref. 5). It is not clear how the activity of angiotensin II in the body is terminated. The inactivation of angiotensin by enzymes in blood has been extensively studied *in vitro*<sup>6,7</sup> as has its inactivation by homogenates of tissues such as intestinal mucosa, kidney, pancreas, spleen and liver<sup>8</sup>. The inactivation of angiotensin II has been studied *in vivo* either by injecting isotopically labelled angiotensins<sup>9,10</sup> or by using the pressor effect of the angiotensin II as a bioassay after the substance has passed through a particular vascular bed<sup>11,12</sup>. One of these methods<sup>9</sup> puts the half-life of angiotensin II *in vivo* between 10 and 37 h, a surprising figure in view of a 70 per cent removal in one circulation through the liver<sup>11,12</sup>.

We have used the blood-bathed organ technique<sup>13</sup> for continuous assay of angiotensin II in the circulation of dogs<sup>14,15</sup> and have estimated the half-life of some angiotensins in the circulating blood. We have also studied the removal of angiotensin II by a number of vascular beds. Some of these results were presented to a meeting of the British Pharmacological Society on April 7, 1967.

The assay organs were a rat stomach strip<sup>16</sup> and two rat colons<sup>14</sup>; these were suspended in polypropylene chambers and superfused<sup>17</sup> in series with Krebs solution while the dog was being prepared. Their movements were recorded on a kymograph by auxotonic levers<sup>18</sup> which produced a magnification of 16:1 with a load of 1-3 g on the tissues. All three organs were contracted by angiotensin, the rat colons much more strongly than the rat stomach strip. The latter was included in the assay system to detect catecholamines which, if released, would relax it<sup>19</sup>. One of the rat colons was perfused intraluminally with propranolol (1 mg/ml. at 0.1 ml/min) to prevent any relaxant effects of catecholamines which would otherwise interfere with the contraction induced by angiotensin.

Dogs of either sex weighing 5-31 kg were anaesthetized with halothane delivered from a Goldman vaporizer; anaesthesia was then maintained with chloralose (100 mg/kg intravenously) and supplemented when necessary with pentobarbitone (5-10 mg/kg, either intramuscularly or intravenously). The trachea was cannulated and the lungs were ventilated mechanically. Polyethylene cannulae were tied into a femoral or carotid artery and a femoral or jugular vein for removal and replacement of blood. Mean arterial blood pressure was also recorded on a kymograph with a mercury manometer attached to a side arm of the arterial cannula.

Heparin (1,000 IU/kg) was injected intravenously and the assay organs were then superfused with arterial blood delivered by a roller pump of constant output at 15 ml/min. The blood then collected in a reservoir and was returned to the dog either by gravity or by a second channel in the roller pump. The assay system could be calibrated by infusing angiotensin II into the stream of blood after it had left the dog; thus an infusion of 15 ng/min into a flow of 15 ml/min would give an absolute change of concentration of 1 ng angiotensin/ml. The assay system could also be calibrated by intravenous or intra-arterial injections into the dog, as described later.

### Inactivation of Angiotensin in Circulating Blood

The inactivation of angiotensin by blood was measured by passing the blood through a length of silicone tubing of 3 mm internal bore and 45 ml. capacity immersed in a water bath maintained at a temperature of 37°C. The arterial blood first circulated through this incubating circuit and then superfused the assay organs (Fig. 1). Thus, by infusing angiotensin at different points in the incubating circuit the drug would be in contact with the blood for known periods of time before reaching the assay tissues. For example, the responses of the rat colons to the same rate of infusion of angiotensin incubated with the blood for 1, 2 or 3 min could be compared with, and bracketed between, infusions of angiotensin given close to the tissues. The inactivation could then be calculated by plotting dose/response curves.

The assay system was sensitive to changes in the concentration of angiotensin of from 0.25 to 5 ng/ml. blood

Table 1. HALF-LIFE OF THREE ANGIOTENSINS

Expt.	Synthetic Asp <sup>1</sup> -NH <sub>2</sub> -Val <sup>5</sup>	Horse and Hog Asp <sup>1</sup> -Ileu <sup>5</sup>	Bovine Asp <sup>1</sup> -Val <sup>5</sup>
1	190	190	—
2	117	174	180
3	97	156	260
4	180	212	405
Mean	146	183	282

Values (in sec) and means refer only to the four dogs in which these multiple estimations were made. Further estimations with the synthetic angiotensin amide alone give an overall value (mean  $\pm$  S.E.) of 113 sec  $\pm$  10.7.

and the half-life of the angiotensins in the blood was measured within this physiological range<sup>20</sup>. Three angiotensins were used: synthetic angiotensin II amide (Asp<sup>1</sup>-NH<sub>2</sub>-Val<sup>5</sup>-angiotensin II; 'Hypertensin', Ciba), subsequently referred to as synthetic angiotensin; the natural horse and hog angiotensin (Asp<sup>1</sup>-Ileu<sup>5</sup>-angiotensin II) and the natural bovine angiotensin (Asp<sup>1</sup>-Val<sup>5</sup>-angiotensin II). A typical assay in which the half-life of synthetic angiotensin was estimated is illustrated in Fig. 2. At first, calibrating infusions of 40, 80 and 40 ng/min were given close to the tissues. An infusion of 80 ng/min incubated with the blood for 180 sec gave the same response as 40 ng/min given close to the tissues. When 80 ng/min was incubated with blood for 120 sec the responses of the tissues were between those given by 40 and 80 ng/min in the close position. Thus, in this experiment, the half-life of synthetic angiotensin was 180 sec.

In four experiments the half-lives of three different angiotensins were estimated (Table 1). Ileu<sup>5</sup>-angiotensin had a longer half-life (mean of 183 sec) than synthetic angiotensin (146 sec) and Val<sup>5</sup>-angiotensin had an even longer half-life (282 sec). Although there was considerable variation from dog to dog in the values of the half-lives, the same general pattern was observed in each individual experiment. Insufficient samples of Ileu<sup>5</sup>- and Val<sup>5</sup>-angiotensin were available to do more comparative experiments. The half-life of synthetic angiotensin in blood was, however, measured in eleven more experiments. The overall mean value was 113 sec (standard error of mean  $\pm$  10.7). In three of these dogs, the half-life was measured three times during the experiment and the same result was obtained each time. Thus the half-lives appear to vary from dog to dog but not in the same dog. When synthetic angiotensin was incubated for 180 sec with Krebs solution in the external circuit instead of blood, there was no loss of activity, showing that the inactivation was due to blood. In one experiment, the incubation circuit was cooled to 5°C and the blood re-heated before superfusing the tissues. The inactivation of synthetic angiotensin was substantially reduced.

When incubated *in vitro* with rat plasma<sup>6</sup>, synthetic angiotensin had a half-life of less than 120 sec, and that of Val<sup>5</sup>-angiotensin was longer. When incubated with

Fig. 1. Blood-bathed organ technique. The diagram shows the assay tissues and the incubation circuit for the estimation of the half-life of angiotensin in blood. The rate of flow of blood through the external circuit is 15 ml/min. A, Rat stomach strip; B, rat colon; C, rat colon ( $\beta$ -blocked); D, propranolol in.

Fig. 2. Inactivation of synthetic angiotensin by circulating blood from a 10 kg female dog anaesthetized with chloralose. Carotid arterial blood was superfused at 15 ml/min over a rat stomach strip (A) and two rat colons (B and C). The angiotensin was infused either close to the tissues or into the incubation circuit to allow contact with blood for two periods of time. Incubation of 80 ng/min for 180 sec reduced the activity to that of 40 ng/min, whereas incubation for 120 sec gave responses intermediate between 40 ng/min and 80 ng/min. In this experiment, the rat stomach strip was unusually responsive to angiotensin.

human plasma, however, synthetic angiotensin had a half-life of 10–20 min<sup>21</sup>.

### Disappearance of Angiotensin in One Circulation through Various Vascular Beds

When angiotensin is infused into the arterial supply to a vascular bed, some of it disappears from the blood and the remainder escapes into the venous effluent, thereby reaching the general circulation. This angiotensin can be assayed by matching the responses of the blood-bathed organs with those produced by infusions made directly into the blood leaving the vascular bed. For example, when an infusion of 1  $\mu$ g/min into the arterial supply to a particular vascular bed gave the same response on the blood-bathed rat colon as an infusion of 0.5  $\mu$ g/min into its venous effluent, 50 per cent of the angiotensin had been removed in one circulation. In all these experiments sufficient time was allowed for equilibrium conditions to be established, as shown by the assay organs reaching a plateau. The disappearance of synthetic angiotensin was studied in the head, the lungs, the liver, the kidneys, a hindquarter and the lower half of the body. For all these experiments, carotid arterial blood was sampled for the assay system except in experiments on the lungs and head, when femoral arterial blood was used.

**Lungs.** For these experiments a catheter was inserted retrogradely through the right carotid artery so that its tip lay in the left ventricle. Infusions of synthetic angiotensin were made either through this catheter, or into the superior vena cava, thus allowing an estimation of the disappearance of synthetic angiotensin in the pulmonary circulation. One of four such experiments is shown in Fig. 3. Angiotensin was infused at two different rates (0.5 and 1  $\mu$ g/min intra-arterially and intravenously); the responses of the assay organs show that no angiotensin was lost in the pulmonary circulation. Indeed, in none of the four experiments could we detect any loss of angiotensin in the pulmonary circulation. This result contrasts strikingly with the 80–90 per cent removal of bradykinin infused into the pulmonary circulation<sup>22</sup>.

**Head.** A carotid artery was divided and both ends cannulated. The circulation was re-established with a loop of silicone tubing through which infusions were made into the carotid arterial circulation; the other carotid artery was tied. These infusions of angiotensin were compared with those made into a jugular vein. In three experiments, one of which is shown in Fig. 4, 40, 50 and 50 per cent of the infused angiotensin disappeared.

Table 2. DISAPPEARANCE OF ANGIOTENSIN II AMIDE IN VARIOUS VASCULAR BEDS

Vascular bed	No. of experiments	Disappearance mean $\pm$ S.E. (%)
Lungs	4	0
Head	3	47
Liver	7	62 $\pm$ 4.3
Hindquarter	5	71 $\pm$ 6.7
Kidneys	10	75 $\pm$ 4.1
Body below diaphragm	10	76 $\pm$ 4.1

**Liver.** A catheter was inserted into a splenic vein and advanced so that its tip lay in the portal vein. Infusions of angiotensin into the portal circulation were then compared with infusions into the superior vena cava (Fig. 4). In seven experiments 62 per cent (standard error of mean  $\pm$  4.3) of the infused angiotensin disappeared in the portal circulation.

**Hindquarter.** A catheter was introduced retrogradely through a ligated femoral artery so that its tip lay just above the bifurcation of the aorta. The venous catheter was introduced into the femoral vein on the same side and advanced the same distance as the arterial catheter. In five experiments 71 per cent (standard error of mean  $\pm$  6.7) of the infused angiotensin disappeared in the hindquarter (Fig. 4).

**Kidneys.** Renal arterial infusions were given in one of two ways. In the first, fine catheters or needles were inserted directly into the exposed renal arteries. In the second, a polyethylene catheter was inserted through a femoral artery and advanced up the aorta so that its tip lay just above the renal arteries; the aorta was then ligated around the catheter just below the renal arteries. In ten experiments there was a 75 per cent (standard error of mean  $\pm$  4.1) disappearance when angiotensin was infused into the kidneys (Fig. 4).

**Body below diaphragm.** To find whether the intestines or other abdominal vascular beds contributed to the removal of angiotensin from the circulation, a catheter was advanced up a femoral artery until its tip lay at the level of the diaphragm. Infusions through this catheter thus reached all vascular beds supplied by the abdominal aorta. In ten experiments the disappearance of angiotensin was 76 per cent (standard error of mean  $\pm$  4.1). The results from all the vascular beds studied are summarized in Table 2.

Our results show that synthetic angiotensin is inactivated relatively slowly in blood and that the natural angiotensins are inactivated even more slowly. Although the nature of dog angiotensin is not known it is unlikely to be inactivated very differently from those already tested. If angiotensin was removed only by enzymes in blood, these half-life values would mean that it would recirculate between ten and twenty times before the activity was reduced to half (assuming a circulation time in dogs

Fig. 3. The failure of synthetic angiotensin to disappear in the pulmonary circulation of a 6 kg dog anaesthetized with chloralose. Femoral arterial blood was superfused over a rat stomach strip and two rat colons. This record is from one of the rat colons. Infusions were made near to the right atrium intravenously (I.V.) or into the left ventricle intra-arterially (I.A.). The responses at each rate of infusion show that there was no loss of angiotensin in the passage through the pulmonary circulation.

Fig. 4. Disappearance of synthetic angiotensin in some vascular beds. Each panel is from a separate experiment and shows the responses of a rat colon superfused with arterial blood. The estimation of disappearance has been made by comparing responses to infusions on either side of each vascular bed. The disappearance was: 50 per cent in the head (A), because an infusion of 2.0  $\mu$ g/min into the carotid artery (I.A.) gave a response matched by 1.0  $\mu$ g/min into the jugular vein (I.V.); 75 per cent in the hindquarter (B) because an infusion of 0.2  $\mu$ g/min into the femoral artery (I.A.) was matched by an infusion of 0.05  $\mu$ g/min into the inferior vena cava (I.V.); 60 per cent in the liver (C), because an infusion of 2.5  $\mu$ g/min into the portal vein (I.P.) corresponded to between 1.0  $\mu$ g and 2.0  $\mu$ g/min into the superior vena cava (I.V.); 65 per cent in the kidneys (D), because an infusion of 2.0  $\mu$ g/min into the renal arteries (I.A.) corresponded with between 0.5  $\mu$ g/min and 1.0  $\mu$ g/min into the inferior vena cava (I.V.).

of 15 sec (ref. 23)). 47–76 per cent of infused angiotensin, however, disappears in one circulation in all the vascular beds studied. It would therefore appear that the half-life of angiotensin is about one circulation time. Using a different technique Biron, Mayer and Panisset (personal communication) have also found that 50–90 per cent of angiotensin infused into various vascular beds disappears. Similar results have been found in man, where a 70 per cent loss of angiotensin across the vascular beds of the limbs was reported in one study<sup>24</sup> and an almost complete loss between arterial and peripheral venous blood in patients with renal vascular disease in another<sup>25</sup>.

One of the physiological implications of these results is that the inactivation of angiotensin by blood is much less important in the termination of its activity in the body than its removal by vascular beds. It is also interesting that neither the liver nor the kidneys are any more efficient in removing angiotensin than, for example, the hindquarter.

The present results do not show what happens to the angiotensin after it is removed from the circulation by the vascular beds. The angiotensin which disappears in a vascular bed may not be entirely destroyed but only removed temporarily, to re-enter the circulation at a later stage. In this regard, it would be interesting to compare the rate of decline of angiotensin in the circulation with the rate of decline of its effect in a particular vascular bed, such as the hind legs.

Finally, the negligible removal of angiotensin by the lungs indicates that the pulmonary circulation is extremely selective with regard to the substances which are allowed through it into the arterial circulation. Another peptide, bradykinin<sup>22</sup>, is largely removed by the pulmonary circulation, as are 5-hydroxytryptamine and the prostaglandins.

That adrenaline and angiotensin are not removed by the lungs may be related to their physiological role as circulating rather than as local hormones.

This work was supported in part by a grant from the Medical Research Council.

## Causes and Effects of Columnaris-type Diseases in Fish

Diseases affecting salmon, sea-trout and coarse fish and characterized by the occurrence of skin lesions have been recognized for some time in the rivers of England, Scotland and Ireland. During 1966 there were epidemics in parts of Ireland as well as Cumberland, Lancashire and southern counties of England. The British and Irish governments intervened to control the movement of live fish and eggs from infected areas, and a programme of research was begun to identify the causative organisms and the nature of the diseases. The three communications which follow describe some of the results obtained so far in government-sponsored and independent research.

### Columnaris Disease in Roach and Perch from English Waters

DAVIS<sup>1</sup> described an infectious disease caused by a rod-shaped bacterium with an unusual mode of motility, which was responsible for heavy mortalities among warm-water fishes of the Mississippi Valley. He observed that when scrapings from dermal lesions of diseased fish were placed in a drop of water on a slide, the bacteria collected on the edges to form short column-like masses. He called the causal organism *Bacillus columnaris* and the syndrome columnaris disease. Davis failed to culture the organism, but Ordal and Rucker<sup>2</sup> and Garnjobst<sup>3</sup> both claimed to have isolated an organism from diseased fish similar to that originally described by Davis. They agreed to place the organism in the order Myxobacteriales. Ordal and Rucker<sup>2</sup> described the occurrence of fruiting bodies and spherical to oval microcysts in their cultures on tryptone-agar. Thus they assigned the species to the family Myxococcaceae Jahn and the genus *Chondrococcus*, and named it *Chondrococcus columnaris*. Garnjobst<sup>3</sup>, on the other hand, could not demonstrate the production of microcysts; she therefore placed the organism in the family Cytophagaceae Stanier and named it *Cytophagacolumnaris*.

Anacker and Ordal<sup>4,5</sup> investigated the serological and bacteriocin typing of the organism and quoted several reported incidents of columnaris disease in fish in the United States<sup>6-8</sup>. Although striking differences in virulence were noticed between various strains isolated during several years<sup>9</sup>, water temperature was considered to be an important factor in determining the amount of damage caused by the organism in the fish population. Most outbreaks have been reported during summer months<sup>4</sup>.

During the summer of 1966 freshwater fish in the English rivers suffered considerable mortalities. A number of fish caught from different rivers were examined in this

laboratory and we report here observations of columnaris disease in English roach and perch.

Strains of the organism isolated from fish affected in the outbreak described in this paper were examined by Professor E. J. Ordal and Dr T. Gibson. Ordal (personal communication) found them indistinguishable from the organism he had described as *Chondrococcus columnaris*. Four cultures were sent to him and he demonstrated the complete genetic relationship to his own strains by the method of DNA homology. He did not determine whether the cultures produced the structures interpreted by him as fruiting bodies. Gibson (personal communication) was unable to demonstrate the presence of fruiting bodies or microcysts by the methods that he used, and therefore suggests that the organisms should be placed in the genus *Cytophaga*, but he does not discount the possibility that other conditions could give different results or that the culture he examined could be a mutant with impaired functions. For the purpose of this paper we refer to the organism as *Chondrococcus columnaris* (Davis) Ordal and Rucker, or *Cytophaga columnaris* (Davis) Garnjobst. *C. columnaris* will thus be used to cover both names for the same organism.

In the early stage of the disease there were small haemorrhagic patches, usually on the ventral surface at the base of the fins. The soft inter-ray tissues of the fins and tail showed congestion. Haemorrhagic lesions were also seen around the mouth and sometimes the cartilaginous structures in the area of the head were attacked. Some fish, presumably in the later stage of the disease, showed deep ulcerated lesions with disintegration of the muscular and cartilaginous tissue. Gills were usually normal. In some instances there was evidence of pathological changes in the liver and kidney, particularly the former.

Direct smears from clean haemorrhagic lesions showed long flexuous Gram-negative rods. In some instances a few rounded bodies, probably involution forms, could be seen

A modified Ordal's medium consisting of 0.5 per cent 'Bacto-tryptone' (Difco) and 0.8 per cent agar (Davis) was used for the isolation and cultivation of the organism. The pH of the medium was usually about 7.1 after preparation and did not need to be adjusted; over-dried plates seldom proved to be satisfactory. The organism was easily isolated from haemorrhagic lesions free from macroscopic evidence of ulcerative or necrotic changes, that is, from the attachment of the scale or from a cut surface at the base of the affected fin, and not merely from a swab of the surface. The organism was isolated from the liver and kidney of two diseased fish only. The organism was not isolated from any other internal organ.

*C. columnaris* colonies developed after 48 h of incubation at 22° C or at room temperature on the bench; there was no growth at 37° C. The colonies on tryptone-agar medium were golden yellow to orange in colour, varying in size from tiny yellow specks to larger branching colonies (approximately 3 to 4 mm in diameter). The growth stuck tenaciously to the agar and the colonies were so embedded in the medium that usually small chunks of agar had to be removed along with the colony to ensure growth in sub-cultures. The colony could not be emulsified easily and under the plate microscope it showed branching outgrowths with a central focus. The growth of *C. columnaris* was adversely affected in the inoculated area of the plates if there was heavy growth of contaminants. A Gram-stained smear revealed long, slender rods approximately 0.5  $\mu$  wide and 5  $\mu$  or more long, arranged characteristically to give a false branching appearance; short and rounded bodies were also seen. The organism was catalase and oxidase positive, and produced small amounts of hydrogen sulphide in 0.5 per cent tryptone water. No growth occurred in the usual peptone sugar media.

Fish and Rucker<sup>9</sup> described columnaris disease in salmonid fingerlings in which the fin lesions were accompanied by pronounced hyperplasia of the gill tissues. In the present case, the lesions seemed to be confined to the fins and tail only; gills were not affected although the tissues were not examined histopathologically.

The constant pattern of isolation of this organism from the diseased fish that we examined, and its close resemblance to the NCMB 1038 strain called *Chondrococcus columnaris*, form the basis of this report. Pathogenicity experiments were not carried out, but the many reports in the literature support the role of *C. columnaris* as a fish pathogen. Both Ordal and Rucker<sup>2</sup> and Garnjobst<sup>3</sup> described successful pathogenicity experiments with fish.

Aeromonads (*Aeromonas liquefaciens*) and Pseudomonads were isolated in many instances from the badly ulcerated lesions, often in large numbers. The significance of these organisms in diseased fish, however, was regarded as secondary rather than primary. Their presence in early developing lesions was rare; in such lesions *C. columnaris* was the predominant organism.

We thank Professor E. J. Ordal, Dr T. Gibson and Dr S. P. Lapage for their help. We also thank the Fishery Establishments of the Ministry of Agriculture, Fisheries and Food for their collaboration.

### Species of *Corynebacterium* and *Pasteurella* isolated from Diseased Salmon, Trout and Rudd

THE carcasses of eleven salmon and five trout from many different areas in the United Kingdom were examined between September and December 1966. Of these the carcasses of five salmon and one trout appeared normal, and most of the fish were found to contain large numbers of eggs.

Almost all the diseased fish showed dirty grey areas of discoloured skin, up to 2 in. in diameter, on the body. They were rounded in outline and slightly raised. Pigmentation of the cutaneous lesions varied. The consistency was superficially firm, overlying an area of subcutaneous haemorrhage and a small amount of serosanguineous fluid was present in some. Ulceration of the jaw, the fins and the tail was seen in a few fish. A white fungus covered the lesions in some fish which at places was tinged with blood, thus presenting a velvety appearance. In one fish a tumour-like growth about 0.5–1 cm across was present on each of the two dorsal fins and the tail. Histopathological examination showed these tumours to be pigment-free, undifferentiated melanomas with evidence of malignancy. Visceral lesions included some non-specific degenerative changes in the liver and intense congestion of the spleen. The kidneys, in most instances, were dark, almost chocolate coloured with a soft pulpy consistency. Histologically the glomerular tufts showed congestion and/or an unusual degree of pigmentation, probably melanin, in some cases. Membranous deposits of the type described by Smith<sup>1</sup> on the surface of the kidneys in so-called Dee disease were not seen.

Direct smears from the heart, liver and spleen showed almost complete absence of organisms. Moderate numbers of a Gram-positive coccobacillary organism together with many other Gram-negative and Gram-positive bacilli of varying morphology were seen in smears from the skin lesions. Smears made from the kidneys, however, invariably showed an abundance of Gram-positive coccobacillary organisms with a fairly uniform morphological appearance, some of which seemed to occur intracellularly. The media employed during initial isolation of the causative agent were horse blood agar, Ordal and Earp medium<sup>2</sup>, Dorset egg medium and a modification of Ordal agar. A Gram-positive coccobacillary organism, similar in morphology to that seen in the direct kidney smears, was isolated from the kidneys only of five of the ten diseased fish and from the kidneys, liver and skin lesions of another fish. The description of the organism is given below.

Growth on horse blood agar at 22° C and 30° C was poor, the colonies being less than 0.5 mm in diameter after 48 h of incubation. No growth occurred at 37° C. The organism was a facultative anaerobe. The colonies were non-haemolytic, smooth, entire, transparent and easily emulsifiable. It was a non-motile, Gram-positive rod, measuring 0.5–0.7  $\mu$  × 2–2.5  $\mu$ . Acid but no gas was produced in glucose, maltose, sucrose, lactose, mannitol, sorbitol and salicin. Nitrate was not reduced. It was MR-positive and catalase positive, but indol, hydrogen sulphide and oxidase production were all negative.

Ordal and Earp<sup>2</sup> described the cultural properties of the aetiological agent of "kidney disease" in salmonid fishes and which they regarded as a species of *Corynebacterium*. Smith<sup>1</sup> reported the occurrence of "Dee disease" and concluded that the causal organism was similar to that described by Ordal and Earp<sup>2</sup>. The strain of organism isolated in the present episode, however, appears to be significantly different in cultural characteristics from the organism reported by these workers. Gray and Killinger<sup>3</sup> reported Listeric infection in pond-reared rainbow trout fed with meat from a donkey which had died of an

undetermined cause. They mentioned that the strains of *Listeria monocytogenes* isolated from these fish were somewhat different from the typical strains of this species, but they did not say in what way. Lapage has suggested (personal communication) that our isolate is related to *L. monocytogenes* as the demonstration of motility in cultures of this species was sometimes difficult. Seeliger (personal communication), after intensive investigation of the organism, did not share this opinion and classified it as an unidentified species of *Corynebacterium*.

Experimental infection of goldfish was attempted with the filtrate, as well as with the mashed-up whole kidney, taken from a naturally diseased salmon, but this was not successful. There was no mortality in the test fish in 3 months, after which the experiment was terminated.

An unusual number of fish were found dead in a connecting series of lakes in Sussex during January 1967. Eleven carcasses (9 rudd, 1 chub and 1 perch) were submitted for examination by the Kent River Authority on January 31, 1967. Seven rudd, 1 chub and 1 perch were examined. Another batch of eleven rudd arrived on February 3, 1967, of which eight were examined.

The perch showed no evidence of disease. The chub had lesions similar to those seen in rudd and described below. There were depositions of greyish brown fungus at two, three or more sites on the body of the fish, usually near the base of the fins and the root of the tail, each covering an area of approximately 0.5–1 cm. The skin at these sites was debilitated, discoloured in appearance and soft in consistency, overlying an area of haemorrhages in the musculature underneath; there was no fluid. Microscopic examination of the skin lesions showed the presence of cellular debris, blood cells and bacteria. The gills were congested and had a soft consistency, particularly near the posterior border. The liver, spleen and kidney showed intense congestion.

From twelve of the seventeen fish examined, twenty-one strains of a small Gram-negative bacillus were isolated from the liver, kidney and skin lesions.

In some instances, cultures from the liver and the kidney yielded an almost pure growth of this organism on horse blood agar and on the modified Ordal agar. The organism grew as tiny, non-haemolytic, dew drop-like colonies on horse blood agar at 22° C and 30° C in 48 h; there was no growth at 37° C. The colonies had a margarine-like consistency. The growth was relatively poor on nutrient agar and the colonies were transparent and rough. It was a non-motile, Gram-negative organism with a fairly uniform morphology. Acid but no gas was produced in glucose, sucrose and mannitol; there was no change in maltose, lactose, sorbitol, salicin and dulcitol. The organism did not utilize citrate and failed to grow in potassium cyanide. It showed a negative reaction to malonate and gluconate, and did not produce decarboxylases. It was catalase negative and weakly oxidase positive. The organism seemed closest to the *Pasteurella* group, although it is not typical of any of the recognized species (personal communication from Carpenter). Smith (personal communication), after extensive investigation of the organism, also expressed a similar opinion, although he observed minor differences in certain cultural and biochemical properties.

The present isolate appears to differ slightly from the organism described by Snieszko and his colleagues<sup>4</sup>, who reported the isolation of a bacterium representative of the genus *Pasteurella* and believed it to be the cause of an epizootic in white perch.

The constant pattern of isolation of this organism and its presence in large numbers in the liver and kidney of the diseased fish in almost pure culture have led us to believe that this could be the aetiological agent. The intense congestion of the viscera with an abundance of this organism suggests that the disease was probably of a septicæmic nature. The fungus (identified as belonging to the genus

*Saprolegnia*) would attack the debilitated sites of the skin as a secondary invader.

*Aeromonas liquefaciens* and a species of *Pseudomonas* were also isolated from the skin lesions as well as the viscera of a few fish. Their complete or relative absence from the internal organs of the majority of the diseased fish, however, suggested their role to be of secondary rather than primary significance.

We thank Dr K. P. Carpenter and Dr Lapage, Colindale, and Dr J. E. Smith, Battersea, and Dr Seeliger, Hamburg, for their help.

### Serum Protein Changes in Diseased Atlantic Salmon

SINCE 1964 there have been outbreaks of unusual disease among salmon in some Irish and English rivers. It is not established whether the disease is the same in the two countries. The disease in Irish rivers has been designated ulcerative dermal necrosis and is characterized by, first, the appearance of white patches on the head, trunk and fins; then, the secondary infection by fungal growth; and eventually, the ulceration of the affected areas, particularly the head, fins and eyes. The cause of the disease is as yet unknown.

Total amounts of serum protein and electrophoretic patterns of the sera from diseased and from healthy salmon have been compared during an investigation of the blood of fish affected with ulcerative dermal necrosis. Marked differences have been found between the sera from healthy and diseased fish.

Twenty-seven diseased (SD1–SD27) and five healthy salmon (SN1–SN5) were obtained alive from the River Lee in County Cork between July 1966 and March 1967. The diseased fish included eleven males and sixteen females, weighing from 3 lb. 12 oz. to 22 lb. The healthy fish included two males and three females weighing from 4 lb. 8 oz. to 8 lb. 2 oz.

The concentration of serum protein was smaller in diseased than in healthy salmon. The total concentrations measured in two healthy fish (SN4 and SN5) were 6.84 g per cent and 5.76 g per cent respectively. Total concentrations of serum protein in diseased salmon varied widely, from 2.88 g per cent up to normal amounts (Table 2). The degree of hypoproteinaemia could be correlated roughly with the extent of the disease. Some variation in the concentration of serum protein is to be expected in healthy salmon, because the fish in fresh water metabolize body reserves built up during life in the sea. It seems likely, however, that the decrease in the concentration of protein observed in the diseased fish was largely caused by the salmon disease: (a) one of the healthy fish (SN4), which had been upriver for 4–5 months as shown by scale readings, nevertheless showed a total concentration of serum protein of 6.84 g per cent; and (b) a number of the fresh-run but diseased fish showed small concentrations of serum protein, which could not have been explained as a result of fasting, for example, SD13, SD14 or SD24 (Table 2).

The serum electrophoretic pattern of diseased salmon differed from that of healthy fish. Characteristic change

in some of the fractions could be correlated roughly with the concentration of serum protein.

The pattern of salmon serum protein established from the five healthy fish showed five major fractions, designated B to F in order of increasing mobility (Fig. 1a). The percentage protein in each fraction, obtained by scanning the electrophoresis strips, is shown in Table 1. When a sufficiently large volume of serum was fractionated three fractions of low mobility, A1, A2 and A3, were usually faintly apparent. The following minor fractions were sometimes apparent: *cd* (intermediate in mobility between C and D) found in SN5; *de* found in SN1 and SN2; and *ef* found in SN3.

There was considerable variation in the pattern of serum protein among the diseased salmon. The trend of change from the normal emerged when a large number of sera had been examined.

Among the major fractions B-F in the sera of the twenty-seven diseased fish, fractions B and C remained relatively constant in mobility and quantity; fraction D, a dense diffuse band in healthy fish, tended to disappear. In diseased fish showing a relatively large concentration of serum protein, the E, and more markedly the F bands, showed an increase; in some cases an *ef* band, and in some cases a *cd* band, were evident (Fig. 1b and c). Curiously in diseased fish which had a small total concentration of protein the E and F fractions tended to disappear together with the D fraction, and there was no evidence of fractions *ef* or *cd* (Fig. 1d). Thus what happened to E and F was apparently related to the ability of the diseased fish to produce serum proteins, as indicated by the concentrations of serum protein. The changes in these

fractions in all the diseased fish examined are indicated in Table 2; for purposes of comparison each fraction is expressed as a percentage of the sum of B and C for each fish.

A derangement of serum protein metabolism was suggested by the above results, and so samples of the liver, spleen and kidney of healthy and of diseased fish were compared histologically. I found no generalized histological difference. There are, however, scattered necrotic foci in the livers of at least some salmon with ulcerative dermal necrosis (unpublished results of K. Strickland).

There was no correlation between susceptibility to the disease in salmon, and the length of time which each had spent in the sea or in fresh water, as shown by the scale readings.

The decrease in the concentrations of serum protein in the diseased salmon may be a non-specific response to disease, because (a) one salmon, SD16, which did not have the disease, but which was heavily infected with fungus, showed a total concentration of serum protein of only 3.6 g per cent; (b) a similar decrease in the total concentration of serum protein was observed previously in pike with lymphosarcomatous growths<sup>3</sup>; and (c) Flemming<sup>4</sup> has reported variation in serum protein concentrations in diseased carp.

The changes in the individual protein fractions D, E, F and the development of the *ef* and *cd* fractions in salmon with ulcerative dermal necrosis may be specific effects. This remains to be established. If the changes prove to be specific they may be useful in the diagnosis of ulcerative dermal necrosis, and may provide a clue to the nature of the disease. Further investigation of the concentrations of protein and the electrophoretic patterns of sera from healthy and diseased salmon is in progress to establish (a) the range of variation in healthy salmon; (b) the range of variation in salmon with ulcerative dermal necrosis and its statistical correlation with the extent of the disease; and (c) the range of variation in salmon with other identifiable diseases, for example, furunculosis.

I thank the Fisheries Division, Department of Agriculture and Fisheries, Dublin, for carrying out scale readings on each of the salmon.

## ASTRONOMY

## Graphite as Interstellar Matter

GRAPHITE consists of hexagonal crystals. Thus the optical constants depend on the direction of the incident light. For light with an electric vector parallel to the basal planes of the crystals graphite behaves like a metal. In the perpendicular direction, for light propagation through a crystal with an electric vector along optic axis, it behaves like a dielectric particle. Many calculations on graphite as interstellar matter have been made. In these cases the electric vector is in the basal plane. Lenham and Treherne have measured the optical constants for

Fig. 1. The optical conductivity against wavelength for graphite with dielectric behaviour.

Fig. 2. The real part of the dielectric constant against wavelength for graphite with dielectric behaviour.

Fig. 3. Computed  $Q$  extinction curves for different radii.

Fig. 4. Observed extinction curves.

graphite with the electric vector along the optic axis (Figs. 1 and 2)<sup>1</sup>. These figures show a sharp minimum in the optical conductivity  $2nk/\lambda$  at a wavelength  $\lambda = 0.64\mu$  and a maximum at the same wavelength in the real part of the dielectric constant  $n^2 - k^2$ . In the computer programme of  $Q$  extinction for spherical particles, " $n$ " and " $k$ " have to be used. They are calculated from  $2nk/\lambda$  and  $n^2 - k^2$  at different wavelengths. The optical constants " $n$ " and " $k$ " have sharp maximum respectively minimum at  $\lambda = 0.64\mu$ , which produces the typical appearance of the  $Q$  extinction curves (Fig. 3). The diagram shows a

broad and deep depression around  $\lambda = 0.64\mu$  between the wave-numbers  $1.5\mu^{-1}$  and  $2.0\mu^{-1}$  for different particle radii. No other material with a similar appearance has been reported which could be interstellar grains. Pure ice is also a dielectric material, but both " $n$ " and " $k$ " are independent of wavelength and give no depression in the  $Q$  curves.

In several observed extinction curves Whiteoak (Fig. 4)<sup>2</sup> has noticed a depression in the range  $1.6\mu^{-1}$ – $2.0\mu^{-1}$ . According to Whiteoak, "it apparently is real, because it is not present in the energy continua of the little-reddened stars".

If interstellar matter consists of graphite grains, all these particles probably have not the same orientation, which means that some of them behave like dielectric particles, some like metals. The depression in the observed extinction curves can be caused by graphite particles with such an orientation that the behaviour is like that of a dielectric particle. Let us assume, for the sake of simplicity, particles orientated at random. Such particles will give a resulting extinction with a shallow depression, because "metallic" graphite has no depression and the resulting extinction is an average value. That would give better agreement with the reported observations. Different combinations of ice and graphite will probably also give a suitable depression.

## PLANETARY SCIENCE

### Muon Solar Daily Variation at a Depth of 60 Metres Water Equivalent

THE solar daily variation of the underground secondary cosmic ray intensity has shown remarkable changes in phase and amplitude during the recent solar minimum.

Observations at the Holborn Underground Station in London with semi-cubic telescopes show that the solar diurnal wave remained virtually constant in amplitude and phase from November 1960 to July 1964. Table 1 summarizes the results for the relevant periods of operation. The errors quoted are standard deviations calculated from the scatter of monthly groups of data.

In the middle of 1964, the time of maximum intensity,  $T_{\max}$ , changed from an average value of about 14 h, as shown in Table 1, to about 06 h and remained near the latter value until the middle of 1966. This early time of maximum was also obtained with independent cubical telescopes pointing due east and north at  $45^\circ$  to the zenith, which came into operation in October 1964. Table 2 shows the results for the calendar year 1965, roughly corresponding to the period of maximum ground level neutron intensity observed at Deep River during the recent sunspot minimum.

Table 1

Period	Direction	Counts/h	Amplitude of diurnal wave (per cent)	$T_{\max}$ (h local time)
Nov. 1960–Oct. 1961	Vertical	50,000	$0.023 \pm 0.013$	$14.3 \pm 2$
Nov. 1961–Oct. 1962	"	50,000	$0.020 \pm 0.013$	$13.8 \pm 2$
Aug. 1963–July 1964	"	150,000	$0.016 \pm 0.007$	$13.3 \pm 1$

Table 2

Period	Direction	Counts/h	Amplitude of the solar wave (per cent)	$T_{\max}$ (h local time)
Jan. 1965–Dec. 1965	Vertical	50,000	$0.024 \pm 0.013$	$5.3 \pm 2$
" "	East	35,000	$0.043 \pm 0.013$	$2.0 \pm 1$
" "	North	35,000	$0.023 \pm 0.013$	$1.5 \pm 2$

The averaged results for the period November 1960–July 1964 are plotted on a harmonic dial in Fig. 1, together with the results for 1965. The latter data are clearly inconsistent with a diurnal wave having  $T_{\max} = 1400$  h as in the period 1960–1964, but they are consistent with the calculated aberration effect caused by the orbital motion of the Earth<sup>1</sup>. This has a maximum amplitude of 0.055 per cent at 0600 h external to the geomagnetic field. After allowing for geomagnetic deflexion the predicted and observed vectors shown on the harmonic dial for the east, north and vertical directions are seen to be in good agreement, which suggests that there is only a small contribution from atmospheric temperature variations.

Comparison of the observed data with the calculated variation expected on the basis of the usual "corotation" model<sup>2-4</sup> for the origin of the solar anisotropy shows that the upper limiting rigidity ( $R_{\max}$ ) for corotating particles must have fallen to 70 GV or less during 1965. Correction of the October 1960–July 1964 vertical data for the orbital motion effect gives agreement with the corotation model, for this period, if  $R_{\max} = 130$  GV (assuming a maximum free space amplitude of 0.4 per cent).

Fig. 1. Harmonic dial in local time, with scale in per cent. Vectors  $E$ ,  $N$ , and  $V$  are the calculated orbital motion effects for east, north and vertical telescopes, respectively. Points marked  $E$ ,  $N$  and  $V$  are the observations for 1965, with their associated standard deviation circles. The point marked  $V$  is the average of vertical observations for the period November 1960–July 1964. The dot-dash curves are the loci of the end-points of the calculated vectors caused by the "corotation" effect; the dots are marked with the corresponding  $R_{\max}$  values (in GV).

Recent data suggest that the time of maximum has returned to 1400 h local time, although this is difficult to establish with certainty from the limited amount of available data. Annual means of the solar diurnal variation have been used to eliminate distortion by possible sidereal effects.

It is interesting to note that during the year 1965 when the underground recorders at Holborn were showing the anomalous early time of maximum, the neutron monitor data from thirteen stations<sup>5</sup> showed a significant reduction in the amplitude of the solar diurnal wave as compared with that of the solar maximum year 1958. There was a similar reduction in the ionization chamber data obtained by the Carnegie Institution of Washington. This reduction in amplitude would be consistent with a corresponding reduction in the amplitude of the free space anisotropy and/or a lowering of the upper limiting rigidity of the variation arising from corotation which have been invoked by us to explain the anomalous behaviour of the underground daily variation. The relatively large changes which occurred underground compared with the rather minor changes in the ground

based data are to be attributed to the vastly different energy responses of the underground and ground level recorders.

So far as is known, the behaviour of the solar diurnal wave as observed by muon detectors has been different during and before the solar minimum of 1964–1965 from that which was observed near the minimum of 1954. During the declining phase of the solar cycle between 1949 and 1953 there were large phase changes in the annual means of the muon diurnal variation at ground level<sup>7</sup>, and near the solar minimum of 1954 there were large phase changes during the course of the year (ref. 6 and others). This pattern of behaviour has not recurred either during the declining phase of the last solar cycle between 1958 and 1964 or around the sunspot minimum of 1964–1965. To this extent the relationship between the cosmic ray solar diurnal variation and solar activity may display a periodicity of 22 yr as well as one of 11 yr, as first pointed out by Thambyahpillai and Elliot<sup>7</sup>.

It would appear that the solar diurnal wave observed underground at Holborn during the period November 1960–July 1964 can be reconciled with the corotation model for the solar anisotropy if the upper limiting rigidity was about 130 GV and the free space amplitude below this limit was 0.4 per cent. The free space amplitude and/or the upper limiting rigidity to which the particles participate in the corotation, however, should have been reduced substantially during 1965 to enable the recorders to register the solar anisotropy caused by the aberration effect which arises from the orbital motion of the Earth around the Sun. There is evidence to suggest that the upper limiting rigidity has again moved to higher values as solar activity increased, but this is not yet conclusive. In contradistinction to the 24 h wave, the semi-diurnal wave has shown no statistically significant variability during the entire period of observation at the underground site.

Drs J. C. Dutt and T. Mathews have contributed to the measurements made with vertical telescopes between 1961 and 1964.

### Magnetic Properties and Petrology of Rocks near the Crest of the Mid-Atlantic Ridge

MAGNETIC and petrological studies have been made on nine dredge samples taken in the course of detailed geological and geophysical investigations of a small area near the crest of the mid-Atlantic Ridge, 22° 30' N., 45° 30' W. (refs. 1 and 2). Samples were taken in 1964–65 on cruises Chain-44 and Washington 1965–1 of the Woods Hole Oceanographic Institution and the Scripps Institution of Oceanography. The magnetic properties of the samples were examined in order to help in the interpretation of observed magnetic anomalies in the area. The remanent magnetizations of twenty cores (2.5 cm by about 3 cm) taken from the nine samples were measured on an astatic magnetometer at the Scripps Institution. Susceptibilities were measured on a susceptibility bridge. The samples were not demagnetized of any isothermal or viscous remanent magnetization components which may have been present. Because all dredge samples were

unoriented, the cores were also unoriented. Care was taken to avoid coring outer visibly weathered zones in some samples.

The rocks examined in this study<sup>3,4</sup> (Table 1) consist of: fresh basalts (10–85, 4–412 and 5–1); mylonized and brecciated basalts which are partially mineralogically reconstituted (2–1, 2–2 and 2–4); and greenstones (greenschist facies metabasalts) (CH-44; 3–126, 3–3 and 3–2).

Values for the magnetic properties of basalt have been available for some time<sup>5,6</sup>. More recently, direct magnetic measurements of submarine lava rock have also been published<sup>7–12</sup>. One recent approach<sup>13</sup>, however, has been to calculate the direction and magnitude of magnetization of seamounts by considering their volumes and associated anomalous fields. Opdyke and Hekinian<sup>12</sup> have reported the magnetic properties of rocks termed "chloritic". Because the detailed mineralogy was not specified it is not possible, however, to say whether the rocks are similar to the greenstones examined here.

The samples and their respective magnetic properties are given in Table 1. The values tabulated for fresh and brecciated basalts agree well with previous values. The samples with the highest susceptibility and intensity are the unaltered basalts because of their content of fresh iron–titanium oxides (mainly platy crystals of titanomagnetite which are locally marginally oxidized to ilmenohaematite, especially in 10–85). The mylonized basalts, which contain as a whole less fresh iron–titanium oxide, have lower susceptibilities. The greenstones, in which all iron–titanium oxide has been replaced completely by sphene, have still lower susceptibilities.

Additional data on the magnetic properties are obtained by inspecting the Königsberger ratio,  $Q$ , the ratio of the magnitude of natural remanent magnetization to that of induced magnetization evaluated here for 0.5 oersted. All the basalts except 5–1 have the same order of magnitude of  $Q$ . Values of the susceptibility, magnetization and  $Q$  ratio for 5–1 are in accordance with values for fresh basalt<sup>7,9,11,12</sup>. By comparison, the  $Q$  ratios for samples 10–85 and 4–412 are rather low. It is mainly the variability in their remanent magnetizations that causes the variation in  $Q$  (ref. 5).

Sample 5–1 was dredged from near the floor of the rift valley. A glassy crust which surrounds it and its fine grain size indicate that it was removed from the top of a flow and thus cooled rapidly. The grain size of a rock is known to govern its remanent magnetization; rocks of finer grain are more magnetic<sup>5</sup>. This accounts for the higher  $Q$  and remanent magnetization of sample 5–1 than of the coarser grained samples 10–85 and 4–412, although the latter have a greater concentration of magnetic minerals (high susceptibilities). Similarly, coarse grained 4–412 has a lower  $Q$  than medium grained 10–85. Variation in the magnitude of remanent magnetization with cooling rate and grain size has been observed in the Mohole basalt by Cox and Doell<sup>8</sup>. They reported a decrease in the remanent magnetization with depth from the top of the section.

Breccia sample 2–4 has susceptibilities and intensities much greater than those of associated rocks 2–2 and 2–1. Its  $Q$  values are similar, however, suggesting a higher magnetic mineral content for 2–4, but a similar thermal history. All these samples have a similar grain size. As alteration proceeds to produce greenstone, the remanent magnetism is destroyed at a far greater rate than the magnetic mineral content, thus reducing the  $Q$  ratio to less than one (samples 125, 3, 2).

It is clear from Table 1 that hydrothermal alteration can significantly decrease the magnetic properties of basalts. This cannot be assumed for other rocks, however. Low grade hydrothermal alteration produces strong but opposite effects on the magnetic properties of basalts and peridotites. These effects are predictable from the oxide mineralogy of these rocks, and from known relations

Station No.	Sample*		Table 1					Volume (cm <sup>3</sup> )	Dredging depths (corrected metres)	Location of sample

\* All of the basalts so far examined are olivine basalts. Complete analyses of four fresh basalts show the unusually low K<sub>2</sub>O content typical of "Oceanic Tholeiites" in terms of normative mineralogy; our samples are olivine tholeiites, they are in the normative ternary olivine-diopside-hypersthene.

between continental aeromagnetic anomalies and oxide mineralogy<sup>14</sup>. Basalts of the "oceanic" tholeiite type, the dominant rock in this area, have been found to contain titanomagnetite with ilmeno-haematite, and hence have high susceptibilities. Hydrothermal alteration breaks down these oxides to sphene and other minerals, thus decreasing the susceptibility and remanent magnetization. On the other hand, fresh peridotites, which are mainly free of magnetite, alter to rocks rich in serpentine and magnetite, which have a higher susceptibility than their parents and may also acquire chemical remanent magnetization.

Possible correlations between regional anomalies and hydrothermal alteration zones might thus be expected. Specifically, strong anomalies might be expected over either hydrothermally altered peridotites, or fresh basalt piles. If a terrain were initially composed of alternate zones of fresh basalts and fresh peridotites, strong anomalies might be expected over the former. If this region then underwent low grade hydrothermal metamorphism, high anomalies would be found over the former peridotite zones, and minima over the basalt zones.

We have determined the magnetic properties of the samples, but not the direction of magnetization. By inspecting the  $Q$  factor, we can determine whether the direction of magnetization can be estimated. Table 1 shows  $Q$  varying roughly from 0.1 to 30.0. The  $Q$  factor involves the ratio of only the magnitudes of the remanent and induced magnetizations, not the direction. The direction and magnitude are taken into account in the vector relation for the anomalous magnetization

$$\vec{J} = k\vec{H}_0 + \vec{J}_n$$

where  $\vec{J}$  = anomalous magnetization vector,  $\vec{H}_0$  = Earth's magnetic field vector,  $\vec{J}_n$  = remanent magnetization vector and  $k$  = susceptibility.

Now, by considering this vector relationship we can see that the maximum angular deviation of the anomalous magnetization vector  $\vec{J}$ , from the direction of  $\vec{H}_0$ , will occur when  $\vec{J}_n$  is perpendicular to  $\vec{H}_0$ . Also the maximum uncertainty in estimating the magnitude of the anomalous field  $\vec{J}$  occurs when  $\vec{J}_n$  is parallel or antiparallel to  $\vec{H}_0$ . Obviously these two situations do not occur simultaneously. With  $Q = 30$  the uncertainty in the magnitude of  $\vec{J}$  is only 3 per cent, but the deviation of  $\vec{J}$  from the Earth's field direction can approach 90°. When  $Q = 10$  the uncertainty in magnitude is only 10 per cent but the deviation is still as high as 78.6°. Thus we can see that anomaly interpretation for the basalts in Table 1 (where  $Q$  is large) is essentially indeterminate if the shape of the disturbing body cannot be closely approximated. Clearly, when  $Q = 1$  the maximum uncertainty in estimating the magnitude of  $\vec{J}$  is 100 per cent, while the deviation may be 45°. When  $Q$  approaches 0.1 the uncertainty in magnitude is a maximum of 10 per cent and the direction will deviate as little as 5.6° from the Earth's magnetic field. This is the case with the greenstones; all magnetization may be assumed induced and in the direction of the Earth's field. The susceptibility is now so low, however, that unless the body is of sufficient size, its anomaly will scarcely be recognizable at the surface of the ocean.

Inspection of the map of magnetic intensity<sup>2</sup> shows that the magnetic anomaly pattern in the area studied

may be related mainly to zones of fresh basalts, alternating with hydrothermally altered zones which perhaps surround fractured zones. This offers an alternative hypothesis in contrast to recent models of sea floor spreading of adjacent north-south trending intrusive bodies with alternate normal and reversed magnetization<sup>15</sup>. To sum up, our results show that vertical zones of hydrothermal alteration of basalts or peridotites along fracture zones should strongly influence the magnetic anomaly patterns over the Mid-Atlantic Ridge.

We thank Jimmie E. Crouch for help in the magnetic measurements, Tj. H. van Andel and V. T. Bowen for supplying the samples, and Tj. H. van Andel for help in preparing the manuscript. Alfred T. Anderson of the US Geological Survey helped with the preliminary investigation of iron-titanium oxides in these rocks. This work was supported by a grant from the US National Science Foundation and by a contract from the Office of Naval Research with the Scripps Institution of Oceanography. Chain cruise 44 was supported by a contract of the US Atomic Energy Commission and the Office of Naval Research with Woods Hole Oceanographic Institution.

## Age of Dolerite Dykes in the Vestfold Hills, Antarctica

THE Vestfold Hills, one of the so-called Antarctic oases, make up an area of exposed rock on the coast of Princess Elizabeth Land, Antarctica. The hills, together with the numerous adjacent islands, form a triangular area about 30 km across. The Australian National Antarctic Research Expedition (ANARE) station Davis is situated in the south-west of the hills at lat. 68° 35' S., long. 77° 58' E.

The Vestfold Hills are composed principally of orthopyroxene-quartz-feldspar gneiss and granulite which contain various amounts of garnet, biotite, and hornblende<sup>1,2</sup>. These metamorphic rocks originally crystallized in the granulite facies, but many now show retrogressive mineral changes<sup>3,4</sup>. Orthopyroxene is commonly converted partly to hornblende and biotite or, in a few examples, to garnet, and some plagioclase is partly converted to carbonate and muscovite. Cataclastic deformation of mineral grains is widespread, leading to partial recrystallization in places. Evidence for migmatization, with local potash metasomatism, has been found at several places<sup>5,6</sup>. The ages of five samples of the country rock have been determined by Ravich and Krylov<sup>5</sup>, and range

Table 1. WIDTH AND STRIKE OF DYKES

Sample No.	Width (m)	Strike
GA5429	9	005°
GA5430	12	171°
GA5431	3.5	110°
GA5432	6	005°
GA5433	2.5	115°
GA5434	2.5	115°

from  $1185 \times 10^6$  years (alaskite granite vein) to  $1525 \times 10^6$  years (migmatite).

A swarm of dolerite dykes has intruded the gneisses. The dykes range in width from a few centimetres up to 25 m, although most of them are less than 3 m wide. Individual dykes can be traced on aerial photographs for distances up to 25 km. Most of the dykes strike between 15° and 30° east of north, and most of the remainder between 35° and 45° west of north; a few trend north or east. Ground observations suggest the dip of the dykes is usually greater than 65°, and that at least some of the dykes striking east-west are slightly coarser than those of other directions. There is no other difference apparent between dykes with different trends, and the dykes probably all belong to one episode of intrusion.

At the request of one of us (I. McL.), Ian Black, geophysicist of the Bureau of Mineral Resources seconded to ANARE, collected in 1964 samples of six conveniently accessible dykes for isotopic age determination. Table 1 shows the width and strike of each dyke from which a sample was collected. Sample GA5429 was blasted from a dyke about 400 metres north-north-east of the hut used for filling meteorological balloons at Davis. The others were obtained by sledge hammer from five different dykes along the southern side of Heidemann Bay, ranging from 1.4 km south-south-west to 1.3 km south-south-east of the station.

The samples are typical of the dykes. They are essentially plagioclase-clinopyroxene rocks, with andesine laths up to 0.8 mm long and pyroxene grains up to 0.3 mm in diameter. Rare plagioclase phenocrysts are zoned from sodic labradorite in the core to calcic andesine at the rim. Clinopyroxene, probably augite, is strongly schillerized and is partly replaced by uraltite (some of which is in turn rimmed by minor biotite) and opaque minerals as well as by orthopyroxene in GA5429 and tremolite in GA5431 and GA5432. GA5429 contains a very small amount of secondary interstitial quartz. Thin sections of GA5430, GA5431 and GA5433 are traversed by zones of cataclasis up to 9 mm wide along which carbonate, garnet, and biotite have replaced the plagioclase and pyroxene.

The samples were analysed by one of us (R. R. H.) at the Department of Geophysics and Geochemistry, Australian National University, Canberra, for rubidium and strontium using the isotope dilution method (see Table 2). The indicated age of the six dykes is  $1030 \pm 220 \times 10^6$  yr at the 95 per cent confidence level, calculated according to McIntyre *et al.*<sup>6</sup>. When plotted on a  $^{87}\text{Sr}/^{86}\text{Sr}$  against  $^{87}\text{Rb}/^{86}\text{Sr}$  diagram, the data for six total rock specimens lie on a straight line (within the experimental error). The rather large possible error of  $220 \times 10^6$  yr comes about because of the extremely low rubidium enrichment and low range in rubidium/strontium ratio in these rocks.

The measured age may represent the time of injection of the dykes, or of a later metamorphism which also

Table 2. ANALYTICAL DATA

Sample No.	Rb $\mu\text{g/g}$	Sr $\mu\text{g/g}$	$^{87}\text{Rb}/^{86}\text{Sr}$	$^{87}\text{Sr}/^{86}\text{Sr}$
GA5429	29.3	163.8	0.5163	0.7131
GA5430	18.9	153.0	0.3567	0.7100
GA5431	14.4	269.9	0.1540	0.7073
GA5432	26.5	153.3	0.4997	0.7121
GA5433	14.2	274.3	0.1492	0.7072
GA5434	14.3	273.9	0.1504	0.7077

<sup>1</sup> Rb =  $1.39 \times 10^{-11}$  yr<sup>-1</sup>.

<sup>2</sup>  $^{87}\text{Sr}/^{86}\text{Sr} = 8.3752$ .

Initial  $^{87}\text{Sr}/^{86}\text{Sr} = 0.7052 \pm 0.001$ .

Age  $1030 \pm 220 \times 10^6$  yr.  
(All samples total rock.)

affected the country rocks. The indicated initial strontium-87/rubidium-86 ratio of 0.7052 is within the accepted limits for the composition of "mantle" material, and does not help to decide whether the rocks were intruded or metamorphosed  $1030 \times 10^6$  yr ago.

Evidence for a  $1000 \times 10^6$  yr event, probably metamorphic, has been obtained at places from 1,000 km to 2,200 km east of the Vestfold Hills<sup>5,7-9</sup>. The petrography of the Vestfold Hills dolerites, however, suggests that they have not been metamorphosed to any extent; the primary textures and uraltization of the pyroxene are typically igneous in all specimens. Although GA5430, GA5431, and GA5433 show evidence of recrystallization along narrow zones of cataclasis, the data for all six samples define the  $1030 \times 10^6$  yr isochron to within experimental error, and we therefore regard this age as the time of injection of the dolerite dyke swarm in the Vestfold Hills.

We wish to thank the members of the ANARE expedition who helped collect the samples, and members of the Department of Geophysics and Geochemistry, Australian National University, for discussion and advice about methods of analysis.

## PHYSICS

### Electron Hole Pairs in the Irradiation of Condensed Systems

RECENT studies on  $\gamma$ -irradiated frozen aqueous solutions at 77° K have led to the elucidation of the kinetics of the reactions of electrons and holes produced by radiation<sup>1</sup>. From this it can be inferred that the nature of the active primary species produced by radiation has to account for the following observations.

The primary species normally undergoes a decay which is kinetically of the first order. Appreciable chemical yields from electrons and/or holes are found only when there are solutes present in the matrix (traps) capable of reacting with both these species in competition with the decay process.

Thus it was concluded that after the initial processes of ionization and excitation subsequent to the passage of radiation, the active intermediate species can be represented as bound electron hole pairs from which the electrons and/or holes can be scavenged by suitable solutes in the matrix.

Recent experimental results on ice and particularly also from electron pulse radiolysis experiments in water in the nanosecond region would suggest that the electron hole pair model proposed for ice is also relevant to aqueous and non-aqueous systems.

The absorption spectrum of pulse irradiated ice<sup>2</sup> (investigated down to temperatures of 200° K) is very similar ( $\lambda_{\text{max}} \sim 720 \text{ m}\mu$ ) to that previously found for water<sup>3</sup>,

and in liquid water, the absorption spectrum of the "hydrated electron" is fully formed after a period of  $\sim 10^{-9}$  sec (ref. 4).

If, as had been previously supposed, one is dealing with an electron trapped in the field of the oriented water dipoles, then on the basis of the theory of the "solvated electron" the absorption maximum in ice should be shifted appreciably towards longer waves, that is, into the infra-red, because the relevant parameter<sup>5</sup>

$$\left( \frac{1}{\epsilon_0} - \frac{1}{\epsilon_s} \right)^2 \quad (1)$$

(where  $\epsilon_0$  and  $\epsilon_s$  are the optical and static dielectric constants respectively) which enters into the theory would become very small because of the low value of the  $\epsilon_s$  of ice for frequencies of the order of  $10^6 \text{ sec}^{-1}$  and even lower for frequencies corresponding to the nanosecond region.

Because the absorption spectra of the unstable intermediate in ice and liquid water are practically identical one must conclude that in both instances one is dealing with essentially the same species. The suggested model of a bound electron hole pair, that is, an exciton of small radius, would be fully compatible with these observations.  $\gamma$ -irradiation of a condensed system would, of course, in the first instance lead to free electrons and holes. After a relatively short time, however, the electrons could be captured by the holes into an exciton of small radial extension. The observed chemical reactions of electrons and holes would then be caused by scavenging by suitable solute molecules of either of these species from this exciton state.

An exciton itself would not make a contribution to electrical conductivity. If, however, for example, the hole is made to react with a suitable scavenger the electron would become more or less free and electrical conductivity could manifest itself.

It is known that in aqueous solutions also, the "hydrated electron" decays by a first order process<sup>6</sup> with a rate constant of the order of  $\sim 10^3 \text{ sec}^{-1}$ . On the basis of the present hypothesis this would now become a question of the lifetime of the excitons. These can decay by radiative or non-radiative processes<sup>7</sup>; one of the latter could be a predissociation according to

leading directly to the formation of some hydrogen atoms and hydroxyl radicals in a relatively short time; this could be the type of process first proposed by Allan and Scholes<sup>8</sup>, corresponding to a yield of  $G \sim 0.6$  in water.

The reason for the relatively long lifetime of the majority of the primarily formed electron hole pairs in the absence of scavengers is not immediately obvious. If they possess a certain amount of kinetic energy, then they could only decay by phonon induced transitions. Such processes may be relatively slow and could lead to long lifetimes under certain conditions<sup>7</sup>.

On the other hand, one has to consider also the possibility that one is dealing here with triplet excitons, and in the case of, for example, water or other systems of low atomic number where there is only little spin orbit coupling, one might expect the triplet state to have a relatively long lifetime<sup>9</sup>.

An exact theoretical calculation of the absorption spectra on the basis of a model of bound electron hole pairs (charge transfer excitons) is difficult because hydrogenic wave functions are only applicable for excitons of large radius. As a first approximation, however, one may use hydrogenic wave functions and the optical dielectric constant  $\epsilon_0 = n^2$ . Another parameter which enters into the theory is the reduced effective mass ( $\mu^*$ ) of the electron hole pair. For water or ice, assuming that the effective mass of the electron ( $m_e^*$ ) and of the hole ( $m_h^*$ ) are about equal and do not differ appreciably from the rest mass of the electron ( $m$ ), that is,  $\mu^* = m/2$ , one obtains<sup>10</sup>

$$\Delta E \simeq 0.19 \frac{me^4}{\hbar^2 \epsilon_0^2} \quad (3)$$

which gives a value of  $\sim 1.6$  eV.

The molecular yields of hydrogen and hydrogen peroxide which were previously attributed to the interaction of two electrons and holes respectively should on the present hypothesis be represented by the interaction of two exciton pairs according to

This would correspond to the interaction of two "excited" water molecules which was proposed previously on the basis of some results on hydrogen-deuterium separation factors from irradiated water-deuterium oxide solutions<sup>11</sup>.

Other experimental observations relating to the "solvated electron" can be satisfactorily explained on the basis of the electron hole pair model discussed here. A full account of these considerations will be published elsewhere.

I thank Professor Sir Nevill Mott for helpful discussions.

### Light Scattering by the Relativistic (Non-linear) Oscillator

A RECENT letter by Hutten<sup>1</sup> contains what in our opinion is an error. The error leads Hutten to the false conclusion that the cross-section of the Rayleigh scattering depends on the amplitude of the relativistic oscillator.

The problem is to find the solution of the non-linear equation

$$\ddot{x} + \omega_0^2 x - \epsilon x \dot{x} = \frac{F}{m_0} \cos \omega_1 t_1$$

where

$$\epsilon = \frac{3}{2} \cdot \frac{\omega_0^2}{c^2}$$

in the harmonic approximation

$$x = A \cos \omega_1 t$$

Assuming the non-linearity to be small, Hutten obtains the following expression for the amplitude of oscillation

$$A = \frac{F_0/m_0}{\omega_0^2 - \omega_1^2 - \frac{\epsilon \omega_1^2}{4} A^2} \quad (1)$$

Hutten concludes that the Rayleigh cross-section may decrease significantly (by several orders of magnitude) when the amplitude of the incident radiation is increased. This is correct if the magnitude of the expression

$$\frac{\epsilon \omega_1^2}{4} A^2$$

in the denominator of equation (1) exceeds the other terms.

It is, however, possible to show that in the case of scattering

$$\frac{\epsilon \omega_1^2 A^2}{4} < |\omega_0^2 - \omega_1^2|$$

always holds, and the cross-section cannot therefore depend significantly on the amplitude of the incident radiation.

Let us evaluate the magnitude of the term

$$\frac{\epsilon \omega_1^2}{4} A^2$$

For the linear oscillator, that is,  $\epsilon=0$ , the amplitude of oscillation and the amplitude of speed are respectively equal to

$$x_{\max} = A; \quad \dot{x}_{\max} = \omega_1 A$$

Consequently, the maximum value (linear oscillator) of the term in which we are interested is

$$\frac{\epsilon \omega_1^2}{4} A^2 = \frac{3}{8} \omega_0^2 \left( \frac{\dot{x}_{\max}}{c} \right)^2 \quad (2)$$

As  $x_m/c \leq 1$ , the effect of magnitude 2 is therefore negligible in the denominator of equation 1, both for Thomson ( $\omega_0 \ll \omega_1$ ) and for Rayleigh ( $\omega_1 \ll \omega_0$ ) scattering.

Even when the incident radiation had a field strength corresponding to the breakdown in a gas ( $10^6$  V/cm) at frequencies higher than  $10^{10}$  c/s

$$x_{\max}/c \ll 1 \text{ and } \dot{x}_{\max}/c \ll 1$$

and a decrease in cross-section cannot therefore be expected as a result of a relativistic effect.

V. A. ZAITZEV  
A. N. LOMAKIN

Institute of Radiotechnique and Electronics  
of the USSR,  
Marx Prospect 18,  
Moscow.

Received March 28, 1967.

<sup>1</sup> Hutten, E. H., *Nature*, **207**, 854 (1965).

Dr E. H. Hutten writes (May 30, 1967):

It is quite true that a relativistic effect can be expected only if the speed of the oscillating particle approaches that of light. The published results giving a decrease in cross-section seemed to point to such an effect, but it is likely that they do not bear this interpretation. I mentioned in my letter that the numerical estimate was doubtful and that other types of non-linearity could produce the same effect.

### Quantum Cosmology

IN cosmology a continuous fluid is used to represent the complex contents of the universe. Homogeneous and isotropic models then show that the universe originated from a space-time singularity of infinite density some  $10^{10}$  years ago<sup>1</sup>. Before accepting singularities of infinite density we must ask whether the continuous fluid models are realistic representations of an early dense universe. Given that an infinite density is possible in a continuous fluid, does it also follow that an infinite density is possible in a fluid consisting of particles?

Taking first the simplest view, we suppose that the fluid consists of classical particles which are elementary in the Democritan sense that they are indivisible. If  $m$  is the particle mass and  $\lambda$  the mean interparticle distance, the fluid density is  $\rho \sim m/\lambda^3$ . In its early stages the curvature

and cosmological constants have negligible effect and the age of the universe is  $t \sim (G\rho)^{-1/2}$ , or

$$t \sim (\lambda^3/Gm)^{1/2} \quad (1)$$

The continuous fluid approximation is valid when the particle horizon<sup>2</sup> is large compared with the interparticle distance, or  $ct \gg \lambda$ . From equation (1) it follows that this condition is also equivalent to  $\lambda \gg Gm/c^2$ , and the interparticle distance is therefore large in comparison with the gravitational length of a particle.

If we now go back sufficiently far in time we arrive at the weird situation of  $ct \sim \lambda$ , or

$$\lambda \sim Gm/c^2 \quad (2)$$

$$\rho \sim c^6/G^3m^2 \quad (3)$$

when each particle is isolated by the particle horizon and its neighbouring particles recede at the speed of light. Going back even further, when  $ct < \lambda$ , we are faced with the dilemma that  $\lambda < Gm/c^2$ , and either the particles are smaller than their gravitational length (which is unacceptable), or else they can be subdivided indefinitely into smaller masses (which is contrary to their property of elementarity). The situation in classical cosmology before  $t \sim Gm/c^2$  is, to say the least, paradoxical<sup>3</sup>.

Attempts to quantize the gravitational field encounter formal and conceptual difficulties<sup>4</sup>, and at present in cosmology only superficial and order of magnitude statements can be made. The "size" of a particle is its Compton wavelength  $\lambda = \hbar/mc$ , and the smallest possible value of  $\lambda$  is the gravitational length  $Gm/c^2$ . The mass and wavelength of a limiting particle<sup>5</sup> are found from  $\lambda^* \sim \hbar/m^*c \sim Gm^*/c^2$ , and are the Planck quantities<sup>6</sup>

$$m^* \sim (\hbar c/G)^{1/2} \sim 10^{20}m_n \quad (4)$$

$$\lambda^* \sim (G\hbar/c^3)^{1/2} \sim 10^{-20}\lambda_n \quad (5)$$

where  $m_n$  and  $\lambda_n$  are for a nucleon mass. The coupling constant of such particles is  $Gm^*/\hbar c \sim 1$  and gravitational and strong interactions are of comparable strength. In the early dense universe the mean particle energy is large and there is a multiplicity of particle states<sup>7</sup>. As a crude approximation we assume that ultimately all particles have the same energy  $m^*c^2$ , and by following the previous arguments or using equation 4 in equations 2 and 3, we obtain the Planck density

$$\rho^* \sim c^5/G^2\hbar \sim 10^{95} \text{ g cm}^{-3} \quad (6)$$

when the age of the universe is  $t^* \sim \lambda^*/c$ , or

$$t^* \sim (G\hbar/c^5)^{1/2} \sim 10^{-44} \text{ sec} \quad (7)$$

and the particle horizon is  $\lambda^* \sim 10^{-33} \text{ cm}$ .

The problem of what happens before  $t^*$  can be resolved roughly in the following fashion, by sacrificing the classical picture of the universe. The magnitude of the fluctuations of the metric, "for a quantum of energy  $mc^2$ ", is plausibly<sup>8</sup>

$$\Delta g \sim g(Gm^2/\hbar c)^{1/2} \sim g\lambda^*/\lambda \quad (8)$$

where  $g$  is a typical component of the metric tensor. The fluctuations are maximum at the shortest wavelength  $\lambda^*$ , and Wheeler sees the metric as having a foamlike structure in which the microcurvature has a scale length of  $\lambda^*$ . This microstructure sets a lower limit of  $\lambda^*$  and  $t^*$  on intervals that can be used meaningfully in a space-time manifold. As long as all intervals are large compared with  $\lambda^*$  and  $t^*$ , classical cosmology can be used to construct models of nested hypersurfaces orthogonal to cosmic time. At time  $t^*$ , however, fluctuations smear the spatial hypersurfaces throughout the age of the universe and the notion of an ordered sequence in time breaks down<sup>9</sup>. The study of the universe at time  $t \sim t^*$  now falls within the little known province of "quantum cosmology". The question of what happens before  $t^*$  is therefore apparently

meaningless; an equivalent answer reminiscent of Greek mythology is primordial chaos.

## CHEMISTRY

### Photosensitized Oxidation of Carbon Monoxide on Semi-conductors supported on Silver

THE recently introduced method of using ultra-violet light to influence reversibly the electronic structure of semiconducting catalysts<sup>1-3</sup> has been extended to a combination of the photovoltaic effect and a catalytic reaction. Illumination with ultra-violet light of thin layers of catalyst, supported on metal, changes the electron distribution in the catalyst reversibly by promoting electrons from the semiconductor into the metal. Other properties, such as porosity and surface area, are unaffected even though they may be changed in doping and alloying. Thus a new method is provided to investigate the relation between electronic structure on the one hand and kinetics and activation energy on the other for catalytic reactions on supported catalysts.

The reaction kinetics and activation energy of the reaction  $2\text{CO} + \text{O}_2 \rightarrow 2\text{CO}_2$  have been investigated in the dark and under irradiation and in the presence of  $\text{Co}_3\text{O}_4$ ,  $\text{NiO}$ ,  $\text{ZnO}$  and  $\text{Ag}$  as well as with the oxides supported on silver. All kinetic measurements have been made over wide ranges of conversion to carbon dioxide in an all 'Pyrex' static system connected with a long necked Erlenmeyer quartz flask as reaction vessel. The reaction was followed by measuring the pressure decrease with time. The catalytic layer covered the bottom of the horizontally mounted vessel. Reaction temperature was measured at the bottom, centre and circumference. An Osram 'HBO 500' high pressure mercury lamp was used for illumination. Due to light absorption by the catalyst, a substantial temperature increase occurred, so that two cooling air tubes, separately controlled by needle valves, were introduced into the furnace, one near the centre of the bottom and one near the periphery. Exactly the same temperatures for corresponding dark and light runs were obtained at all measuring points so that differences of catalytic behaviour between light and dark runs would not be caused by uncontrolled temperature differences but must be the effect of light alone.

Table 1. ACTIVATION ENERGY, PRE-EXPONENTIAL FACTOR AND KINETIC EQUATION

Catalyst	Temperature range (° C)	Plain oxides				Kinetic equation	Supported oxides				Kinetic equation
		(1) Activation energy [kcal/mol]		(2) Log A			(1) Activation energy [kcal/mol]		(2) Log A		
		Dark	Light	Dark	Light		Dark	Light	Dark	Light	
Co <sub>3</sub> O <sub>4</sub>	120-350	9.4	6.0	4.4	1.7	$k_{\text{PCO}}\text{Po}_2^{1/2}$	3.5	1.6	1.6	-0.6	$k_{\text{PCO}}$
NiO	150-250	20.0*	15.2	5.0	3.0	$k_{\text{PCO}}$	40.3	33	7.7	6.0	$k_{\text{PCO}}/p_{\text{CO}_2}$
ZnO	400-600	20.6 <sup>1-3</sup>	10.2	8.3	-0.5	$k_{\text{PCO}}/p_{\text{CO}_2}$ *	9.0	1.8	20.6	9.0	$k_{\text{PCO}}$
Ag	300-550	14.6*	6.0	6.25	1.5	$k_{\text{PCO}}$					

\* In the light  $k_{\text{PCO}}$ .

Kinetic equation was proved by systematic variation of all initial partial pressures. Activation energy was evaluated by plotting  $\log k$  of runs with stoichiometric mixture against  $1/T$  (Arrhenius plot). Log A was extrapolated from the Arrhenius plot for  $1/T = 0$ . Dimensions of A:  $[s^{-1}]$  for first order,  $[s^{-1} \text{ torr}^{-1/2}]$  for 1.5 order,  $[\text{torr/s}]$  for first order with inhibition. A depends on surface area. Because of the preparation of the catalysts in the reaction vessel no BET-areas were measured. All catalysts of the same oxide had approximately the same surface, however, and a change of log A of only  $\pm 0.2$  (at least 7 different layers).

Catalytic layers were prepared by evaporating silver in the presence of 10-20 microns of hydrogen onto the inside bottom of the flask. The oxide in acetone suspension was then painted onto the evaporated silver layer. The reaction mixture was in contact with the oxides only. When the oxide layer did not cover the silver completely, the activation energy of silver was observed. Layer thickness, estimated by weight and geometric coated area, varied from 250 to 2200 Å for both oxide and silver. All layers were transparent when illuminated with the mercury lamp. Illumination was done from the silver side. The transmission of silver layers and spectral distribution of the 'HBO 500' radiation are given in Fig. 1. Even thick silver layers permitted at least 30 per cent of light to pass into the oxide. Catalysts were exposed to 4 runs and then held in the presence of the reaction mixture for one hour to obtain constant activity. Because of dead volume in the neck of the Erlenmeyer flask, a new method of pressure evaluation from the manometer reading was used<sup>4</sup>. Kinetic data and activation energies are given in Table 1.

The principal results are as follows. (1) On plain oxides, illumination of the catalyst significantly lowers the activation energy. Likewise, the pre-exponential factor A is lowered considerably. As a result, the straight lines of the photoactivation energy cross the lines of the dark activation energy in the Arrhenius plot. At temperatures higher than the cross point the absolute rate is higher in the dark; at lower temperatures, the photo-rate is higher. (2) Supporting the oxides on silver completely changes the activation energy, rate constant and reaction order. (3) On supported oxides, illumination of the catalyst considerably lowers activation energy and pre-exponential factor A in two cases (NiO, Co<sub>3</sub>O<sub>4</sub>) and increases it for ZnO. Orders remain unchanged.

Fig. 1. Right scale, curve a, relative spectral distribution of 'HBO 500' in per cent of total radiation. Left scale, per cent transmission of evaporated silver layers. b, 1500 Å thick; c, 800 Å thick; d, transmission of quartz bottom of the reaction vessel.

It should be noted explicitly that the order of dark and light experiments on a catalyst layer has no influence on the kinetics and activation energy, and that dark and light runs may be alternatively measured; both kinds of measurements are strictly reproducible<sup>2</sup>. Promotion of electrons by light seems to be reversible at least as far as catalytic effects are concerned.

These experimental results may be understood in a manner similar to that for doping experiments<sup>1-3,6-8</sup>. The thickness of oxide layers is comparable with the thickness of space charge layers in semiconductors ( $10^{-7}$ – $10^{-4}$  cm)<sup>9</sup>. In the dark, the work functions of silver and of the oxides will determine whether electrons move from silver to the oxide or in the other direction<sup>7,8,10</sup>. The work function of silver is smaller than that of NiO and ZnO<sup>11,12</sup>. Silver emits electrons into NiO and ZnO, and the former, being a p-type semiconductor, shows a higher activation energy for the oxidation of CO (40.3 kcal/mol instead of 20.0). The activation energy of ZnO, an n-type semiconductor, is smaller (9.0 instead of 20.6). The work function of Co<sub>3</sub>O<sub>4</sub> is smaller than that of silver<sup>11,12</sup>. Even in the dark electrons therefore move to the silver, lowering the activation energy of the p-type Co<sub>3</sub>O<sub>4</sub> (ref. 13) (3.5 instead of 9.4). In the light, electrons are moved into the silver because of the photovoltaic effect<sup>14</sup>. The activation energy of the p-type NiO on silver is decreased to 7.7 kcal/mol, that on the n-type ZnO on silver increased again to the original 20.6 kcal/mol and that on the p-type Co<sub>3</sub>O<sub>4</sub> on silver decreased even further to 1.6 kcal/mol.

## BIOPHYSICS

Hexagonal Single Crystal Pattern from the Spore Coat of *Bacillus subtilis*

We have already reported by chemical and X-ray diffraction investigations<sup>1,2</sup> that the spore coat of *Bacillus subtilis* is composed of a keratin-like protein with a crystalline structure. This communication reports the results of an electron diffraction investigation designed to give further information on the structure of the spore coat.

The spore coat preparation used in this work was obtained by disrupting the cleaned spores of *Bacillus subtilis* (Marburg strain) in a Braun cell disintegrator and collecting the sedimentable fraction. The detailed procedure used for preparing the spore coat has been described previously<sup>2</sup>. Selected fragments of the spore coat were examined by direct transmission in a JEM-7 type electron microscope at an applied voltage of 80 or 100 kV. Photographs of the micro and dark images were taken on the same specimen.

Fig. 1 shows the direct image of a fragment of the spore coat. The electron diffraction pattern and the micro-image photograph of this specimen are shown in Figs. 2 and 3 respectively. These photographs show that the electron beam was diffracted by the spore coat fragment itself. That this was so is also supported by the fact that a larger fragment of the spore coat which retained the original shape of the intact spore gave the same diffraction pattern as that in Fig. 2.

As will be seen from Fig. 2, the spore coat fragment gave a hexagonal single crystal pattern which has  $C_{6v}$  diffraction symmetry on the basal plane. The unit cell dimension in the direction of the  $a$  (or  $b$ ) axis was calculated to be 5.35 Å from this diffraction pattern. Because the spore coat fragment was a thin plate, as shown in Fig. 1, and it gave the pattern on the basal plane only, we could obtain no information about the direction of  $c$  axis, in spite of our efforts to tilt the specimen up to 20° in the field of an electron microscope. Accordingly, the space group to which the spore coat crystal belongs has not yet been determined.

Comparing the diffraction pattern of the spore coat with that of  $\alpha$ - and  $\beta$ -keratins which were reported by

Fig. 1. Electron micrograph (direct image) of a fragment of spore coat. ( $\times 40,000$ .)

Fig. 2. Electron diffraction pattern of the spore coat specimen shown in Fig. 1. The diffraction pattern shows a hexagonal symmetry.

Fig. 3. Micro-image photograph of the specimen shown in Fig. 1. The direct image (centre) shows that the electron beam was diffracted by the spore coat fragment.

Astbury and Street<sup>3</sup>, it was found that the structure of the spore coat crystal was different from that of keratin;  $\alpha$  and  $\beta$ -keratins both showed orthogonal symmetries in the diffraction patterns. These results therefore suggest that the structure of the spore coat protein is similar to that of polyglycine II<sup>4</sup>, rather than to the  $\alpha$ -helix<sup>5</sup> or  $\beta$ -pleated structure of silk fibroin<sup>6</sup>.

Although several workers<sup>7,8</sup> have shown that the spore coat fractions from some bacilli contain a small amount of mucopolysaccharide, this substance was recently found by Warth, Ohye and Murrell<sup>9</sup> to be originally present in the residual cortex or cortical membrane, and not in the spore coat. This observation seems to support our concept that the spore coat is constructed from structural protein only.

Fig. 4. Diagrammatic representation of the crystallographic structure of the spore coat showing the crystallographic axes on the longitudinal section of the spore (a) and those on the spore coat fragment (b). The spore coat is wrapped in a layer of single crystals of structural protein.

We have already shown<sup>10</sup> that electron micrographs of ultra-thin sections of the spores of *Bacillus subtilis* often indicate that the spore coat consists of about fifteen lamellae, each about 33 Å thick. These lamellae are considered, on the basis of the present results, to be single crystals of the structural protein.

Fig. 4 is a crystallographic diagram showing the proposed structure of the spore coat of *Bacillus subtilis*. The laminated spore coat (Fig. 4a), in which each lamella is thought to be a single crystal, is shown as a distorted O-shaped ring surrounding the spore core (shaded area). The *c* axis (the direction of the polypeptide chain) was perpendicular to the plate of a laminar crystal, whereas the *a* and *b* axes (the lateral directions of the polypeptide chain) were parallel to it (Fig. 4b). A detailed discussion of this problem will be published elsewhere.

We thank Mr N. Ishida and Mr T. Nobuchi for their technical advice, and Professors S. Akai and H. Harada for making available for this work the electron microscopes in their laboratories. We also thank the staffs of Japan Electron Optics Laboratory Co. Ltd. for their technical assistance. This work was supported in part by a research grant from the Ministry of Education, Japan.

## IMMUNOLOGY

### Allotypic Specificity of Serum Protein in Inbred Strains of Rats

SINCE Oudin's original discovery of allotypes in the rabbit<sup>1</sup> a similar genetically determined intra-species differentiation of plasma proteins has been described in several species<sup>2</sup>. Although most interest was concentrated on immunoglobulins, allotypy is clearly a general biological phenomenon. It provides the biologist in a variety of fields with a useful tool, especially for investigating the molecular structure of proteins and of the genetic

characteristics of the cells producing these proteins. It is therefore important to know the allotypic systems of the experimental animal used.

To our knowledge there has been no report about allotypy in the rat. Perhaps the rat's bad reputation as a producer of precipitating antibodies has delayed the observation which we describe in this communication. This observation has been made during the course of a project in which highly inbred strains of rats, namely, Wistar BB (Department of Anatomy, Birmingham) and black and white hooded (Chester Beatty, London), have been used. Individual rats of the black and white hooded strain were immunized (as control animals for another experiment) in the following way: the animals received weekly intraperitoneal injections consisting of 2 mg of pooled rat serum proteins (Wistar BB) in a volume of 0.25 ml. each, with Freund's complete adjuvant (1 volume of antigen plus 2 volumes of adjuvant containing 2 mg of heat killed *Mycobacterium tuberculosis*/ml.). Four black and white hooded rats were bled a week after the twelfth injection and the sera were tested in 1 per cent agar-gel made up in buffered saline, pH 7.2, against the original material used for immunization (serum of Wistar BB rats). The plates were developed at room temperature for 24 h or longer. Three of the four samples of rat serum showed the presence of an antibody against the material with which they had been injected. The donor of the strongest antiserum (black and white hooded rat No. 24) was then immunized for 3 more weeks and bled out a week later. All the following tests have been performed using this No. 24 rat anti-rat antiserum.

Fig. 1. Precipitation reaction between the rat (black and white hooded) antiserum No. 24 in well 1, and a rat (Wistar BB) pooled serum in well 2.

Fig. 1 illustrates a precipitation reaction between the rat No. 24 antiserum and the pooled rat serum (Wistar BB) used for immunization. Individual serum samples of various inbred strains of rats and mice were examined in the same way; Table 1 summarizes the results. The

Fig. 2. Immunoelectrophoretic pattern of rat (Wistar BB) serum electrophoresed in 1 per cent agar-gel (barbitone buffer, 0.05 molar, pH 8.6) at 15 V/cm for 2 h, and exposed to rat antiserum No. 24.

Fig. 3. Immunoelectrophoretic pattern of the serum from Fig. 2 exposed to rabbit anti-rat serum.

positive reactions were observed with the samples of rat serum from which the immunogen originated—the Wistar BB strain. They also occurred with the individual sera of normal Wistar AA rats, of the cross-breed ( $F_1$ ) Wistar AB and of the albino strain (Gowans). No precipitation, however, was noted between antiserum No. 24 and serum samples of six normal black and white hooded rats, the strain in which the antiserum was produced. This was also true of the single samples from six inbred mouse strains.

The reaction between antiserum No. 24 and a preparation<sup>3</sup> of Wistar BB  $\gamma$ -globulin, as demonstrated by the immunoelectrophoresis patterns (see Figs. 2 and 3), suggests that the allotypic specificity (determinant) being described is located on molecules belonging to the  $\gamma$ -globulin fraction of the serum. 'Sephadex G-200' filtration in 0.5 molar sodium chloride provided further evidence for the active material (antigen) found in the second peak only. We call this rat allotypic specificity (determinant) Ra 1 and the corresponding rat antibody (No. 24) anti-Ra 1.

There is no proof yet for the antibody activity of the molecules carrying the Ra 1 determinants and this should, of course, be investigated further; nor is there any evidence to which sub-class (Fig. 3) of the heterogeneous rat  $\gamma$ -globulin fraction<sup>4,5</sup> these molecules belong. Nevertheless, the reported allotypic specificity may, even at this stage, be of value to research workers looking for biological markers on plasma proteins of the rat.

We thank Professor J. L. Gowans for his generous gift of inbred rats, and Dr June Marchant for inbred mice. This work was supported by the Medical Research Council.

### Cytotoxic and Cytolytic Effect of Mouse Anti-embryo Sera on Ehrlich Ascites Cells

FURUSAWA *et al.*<sup>1,2</sup> have demonstrated surface antibodies common to embryonic cells of the mouse and Ehrlich ascites cells. In these conditions we have investigated, *in vivo* and *in vitro*, the action of the anti-embryo sera of the mouse on cancerous Ehrlich ascites cells.

The mouse anti-embryo sera were obtained by injecting guinea-pigs or rabbits with an entire crushed embryo of ML mouse (0.5 ml.) with 0.5 ml. of complete Freund's adjuvant every 15 days for 60 days. *In vitro*, all sera obtained, in the absence of complement, agglutinated

Ehrlich ascites cells even at weak dilutions (as low as 1/512). On the other hand, cytotoxic activity of different sera varied very much, and we have classified our sera into three categories. (a) These sera can only agglutinate Ehrlich ascites cells; they have no cytotoxic activity even when the serum is not heat-treated. (b) These sera have a cytotoxic effect in the presence of complement, as shown by the trypan blue technique; the cancerous cells impaired by the serum are stained with a 3 per cent solution of trypan blue in Hanks solution. This coloration shows the disorders of permeability of the cellular membrane, although by simple microscopic examination the cells do not seem to be destroyed. We have found in controls that 10 per cent to 20 per cent of ascites tumour cells are coloured after 30 min of incubation with trypan blue. When ascites cells were treated with antiserum to mouse embryo cytotoxic for ascitic cells, 40 per cent to 50 per cent of the cells were stained with trypan blue. Cytotoxic serum without complement did not alter the permeability of the cells as detected by staining with trypan blue. (c) These sera have an immediate distinct cytolytic effect in the presence of complement, which can be seen by direct microscopic examination. Under the influence of the sera, the ascites cells are destroyed in large numbers and are observed to burst. This cytolytic activity is usually stronger than that of the control anti-Ehrlich ascites sera.

Sera (c) are obtained more easily if embryos younger than 12 days old are used for the immunization. On the contrary, embryos older than 15 days cannot induce the formation of cytolytic sera. We should, however, emphasize that we cannot constantly reproduce the cytolytic sera (c) because we do not know all the necessary conditions.

Table 1. SURVIVAL OF MICE CHALLENGED SIMULTANEOUSLY WITH ASCITES TUMOUR CELLS ( $10^7$  CELLS) AND 0.15 ML. OF ANTISERUM TO MOUSE EMBRYO

Antisera and controls (0.15 ml.)	Experiment No.	No. of mice	Immunized animals	Mean survival time (days)
Non-cytotoxic antiserum (a)	1	8	G	14.2
	2	10	G	15.3
	3	12	R	14.7

Antiserum to mouse adult liver	1	15	G	9.6
Antiserum to ascitic fluid	1	15	G	18.1
	2	10	G	14.8
	3	10	R	13.9

G, guinea-pig; R, rabbit.

We were able to demonstrate the cytolytic effect of the anti-embryo sera on Ehrlich cells *in vivo* in two series of experiments. In the first, simultaneous injection of sera (b) or (c) with  $10^7$  cells of Ehrlich ascites in the peritoneum of ML mice caused a prolongation of the average survival rate (which is normally about 15 days) of 1–3 days (with sera (b)) or 4–5 days (with sera (c)). These results have been supported by several experiments as reported in Table 1. These results indicate that antisera against mouse embryo often inhibit tumour growth more effectively than the control anti-Ehrlich ascites sera.

In the second series of *in vivo* experiments we injected intraperitoneally fourteen ML mice on the fourth day of the development of the Ehrlich ascites with 0.5 ml. of undiluted serum. Five animals died during the first 48 h. Four animals showed prolonged survival (after the twentieth day) and showed either mixed ascitic tumours and solid (two mice) or only solid subcutaneous tumours when the ascites cells were inoculated (two mice). The appearance of these subcutaneous tumours indicates that the ascitic cells are largely destroyed by the anti-embryo serum; but on the contrary, the cells which had diffused into the subcutaneous tissue at the time of inoculation of the ascites cells escaped the action of the serum and were able to develop. Such an explanation

has already been put forward by Colter *et al.*<sup>3</sup>, who also observed the appearance of solid tumours after treatment of Ehrlich ascites. We should, however, point out that we were unable to reproduce this experiment with sera (a) or (b). On the contrary, treatment with these sera shortened the period during which these animals survived.

### Haemolytic Plaque Formation by Unimmunized Mouse Peritoneal Lymphocytes

BUSSARD<sup>1</sup> has recently reported that when peritoneal cells from unimmunized mice are incubated at 37° C with sheep red blood cells and complement in a film of carboxymethyl-cellulose gum (CMC)<sup>2</sup>, they produce plaques of haemolysis. He also presented some evidence that this lysis results from the production of antibody.

We have studied this phenomenon in the hope that the system might be useful in investigating the mechanism by which some oncogenic viruses depress immunity<sup>3</sup>. We have confirmed Bussard's observation and attempted to determine the type of cells which actually produce plaques, and the effect on them of anti-mouse immunoglobulin serum (AMiGS). Briefly, in the Bussard system, mouse peritoneal cells are suspended in 2.5 per cent CMC in *tris*-buffered Eagle's medium plus antibiotics, with 5 per cent sheep red blood cells and 10 per cent fresh guinea-pig serum absorbed with sheep red blood cells. The mixture is pressed between a slide and a coverslip, sealed and incubated at 37° C. Plaques of haemolysis are counted microscopically and related to the number of peritoneal cells in the film.

In this system, peritoneal cells from unimmunized adult *BALB/c* mice produced a fairly constant number of plaques, and this property was shared by pleural fluid cells, but not by cells from the spleen, lymph node, thymus or bone marrow. The first plaques appeared after incubation for 15 h and reached a maximum number at 72 h. Controls with inactivated complement, heat-killed peritoneal cells, or isologous mouse red blood cells, were all negative, but in the last case observation was limited to 24 h because of their fragility (M. B., unpublished observation).

Between 98 and 99 per cent of the mouse peritoneal cells are either lymphocytes or macrophages. In order to separate these, we used the ability of macrophages to stick more firmly to surfaces *in vitro* than lymphocytes. Because the macrophages could not then be detached, the original Bussard method had to be modified. Three types of peritoneal cell preparation were made in plastic tissue culture Petri dishes 50 mm in diameter:

(1) *Total population*. The cell suspension was allowed to settle for 3 h at 37° C, and the medium gently removed. A microscopic count showed that about 42 per cent of the cells had the appearance of macrophages.

(2) *Macrophages*. After incubation for 1 h at 37° C, cells adhering to the dish were washed three times at hourly intervals, twice gently, the third time vigorously: about 98 per cent of the remaining attached cells were macrophages.

(3) *Lymphocytes*. The first supernatant removed from (2) was incubated for a further hour, and then transferred to fresh dishes. After the cells had been incubated for a further 1.5 h in order to allow the cells to settle the medium

Fig. 1. Production of haemolytic plaques by different peritoneal cell types. ○, Lymphocytes (~92 per cent pure); ×, macrophages (~98 per cent pure); ●, mixed population (~58 per cent lymphocytes).

was gently removed. About 92 per cent of these cells were lymphocytes.

In each case the cells were covered with a drop of the mixture of CMC sheep red blood cells and guinea-pig serum; a coverslip was pressed on to the drop and sealed. The numbers of plaques per 10<sup>6</sup> cells formed by each type of preparation during incubation for 3 days are given in Fig. 1. The total population gave numbers of plaques similar to those observed when the cells were incorporated into the gum. Very few plaques were formed in the macrophage preparation and these could have arisen from residual lymphocytes. More plaques per 10<sup>6</sup> lymphocytes were formed in the 92 per cent pure preparation than in the mixed population with macrophages.

Several workers<sup>4-7</sup> have shown that the presence of AMiGS decreases the number of haemolytic plaques formed in the Jerne test<sup>8</sup> by mouse spleen cells in the first 2-3 days of immunization and greatly increases it in the later stages.

A rabbit AMiGS which reacted immuno-electrophoretically with all five classes of mouse immunoglobulins was kindly provided by Drs Dresser and Wortis. Dilutions of this serum, or of normal rabbit serum, were incorporated in the gum with peritoneal cells, sheep red blood cells and complement. For comparison, the effects of the same concentrations of sera on the production of plaques by spleen cells from mice injected intravenously with  $2.5 \times 10^8$  sheep red blood cells 2 or 9 days before were also examined. The spleen cells were tested both by the Jerne<sup>8,9</sup> and Bussard techniques. The results are given in Table 1.

The action of AMiGS on plaque production by spleen cells from immunized mice was similar in the Jerne and the Bussard systems, namely a slight to almost complete inhibition (depending on concentration of the serum) at 2 days, and a marked enhancement at 9 days, after immunization. Plaque production by peritoneal cells from unimmunized mice in the Bussard system was inhibited in a similar way to that by spleen cells taken 2 days after immunization. Appropriate tests showed that the inhibitory effect of AMiGS on peritoneal cell plaques was not due to anticomplementary activity or to cytotoxicity. It was abolished by absorption with normal *BALB/c* mouse serum. Normal rabbit serum also had some inhibitory effect (not reduced by absorption with mouse serum) on plaque formation by peritoneal cells from unimmunized mice, and by spleen cells taken 2 days after immunization—another similarity between them.

Bussard suggests that peritoneal cells react to a primary antigenic stimulus because they are a mixed population

Table 1. EFFECTS OF VARIOUS SERA ON HAEMOLYTIC PLAQUE FORMATION

of macrophages and lymphocytes<sup>1</sup>. Our results show that it is the lymphocytes which actually produce the plaques, and this indirectly supports the view that the plaques result from antibody production because there is no evidence that macrophages produce antibodies. Because our purified lymphocyte suspensions contained 8–9 per cent macrophages, however, an essential role for the macrophage cannot be excluded. The inhibitory effect of AMIgS demonstrates that plaque formation by peritoneal cells is mediated by immunoglobulins, and is a further indication that plaques result from the production of antibody. The close parallelism between this effect on peritoneal cells from unimmunized mice and on spleen cells from mice 2 days after immunization suggests that the former, like the latter, produce 19S antibody.

We thank Dr M. H. Salaman and Dr G. L. Asherson for their advice, and Miss J. M. Burke for excellent technical assistance. This work was partly supported out of a block grant from the British Empire Cancer Campaign.

### Allograft Survival prolonged by Heterologous Spleen Cells in 'Millipore' Diffusion Chambers

WE have mixed heat-inactivated lymphoid cells from C57Bl mice with rat spleen cells. The mixture was placed in 'Millipore' diffusion chambers which were introduced intraperitoneally into C57Bl mice. Five days later these animals were grafted with CBA skin. We hoped that the rat cells would produce antibody against antigenic moieties present in the mouse lymphoid cells, and that the antibody would diffuse out of the chambers, inactivate host lymphoid cells and thus depress the immune response of the treated animal. Previous workers<sup>1,2</sup>, employing a rather similar experimental model, have shown that lymphoid cells mixed in diffusion chambers with sheep red cells can produce antibody against the latter. The ability of a heterologous anti-lymphocyte serum to prolong allograft survival is now well established<sup>3-6</sup>.

In each of our experiments spleens from two or three syngeneic female Lewis rats (170–200 g body weight) were pooled, finely minced with scissors on a stainless

steel mesh and irrigated with TC 199 (Difco). Lymphoid cells from C57Bl mice were added to this cell suspension in a ratio of a hundred rat cells to one mouse cell. The mixture of cells was gently centrifuged for 5 min; the sediment was resuspended in a small amount of TC 199 and placed in 'Millipore' diffusion chambers. A volume of 0.1–0.15 ml. of cell suspension was placed in each chamber; the number of cells present on each occasion is indicated in Table 1.

The mouse lymphoid cells used were obtained from the spleen, lymph nodes and thymus of male C57Bl mice (20 ± 2 g body weight). The tissue was cut up into small fragments, suspended in TC 199 and gently homogenized by hand in a glass homogenizer. The suspension of cells was filtered through a stainless steel mesh, centrifuged and washed twice with TC 199. Red cells were lysed by adding 5 ml. of distilled water to the pellet of cells with vigorous agitation for 15 sec, after which 10 ml. of TC 199 was added, and the cell suspension was centrifuged and washed twice with TC 199. The suspension of cells was next subjected to 56° C for 20 min in an attempt to prevent the mouse cells in the chambers from reacting against, and inactivating, the rat spleen cells; we had previously found (unpublished observations) that 56° C for 20 min resulted in very significant reductions in the functional viability of lymphoid cells. Finally, the cells were washed twice more with TC 199 and then added to the suspension of rat spleen cells, as previously indicated.

Diffusion chambers, membranes and cement (formulation 1) were obtained from the Millipore Filter Corporation.

† Animal died with intact healthy graft.

L, Lymph nodes; S, spleen; T, thymus. These letters indicate the tissue of origin of the C57Bl lymphoid cells used. Lymphoid cells from male C57Bl mice (20 ± 2 g body weight) were subjected to 56° C for 20 min. These cells were added to a suspension of spleen cells from syngeneic Lewis rats in the proportion of 100 rat cells to 1 mouse cell. Mixed cell suspensions were placed in 'Millipore' diffusion chambers, and each C57Bl mouse (20 ± 2 g body weight) in the experimental groups received one chamber intraperitoneally. Five days later the mice were grafted with skin from male CBA mice (20 ± 2 g body weight).

The chambers had diameters of 14 mm (outer diameter) and 10 mm (inner diameter) and were 2 mm high. Membranes had an average pore diameter of 100 m $\mu$  (Millipore Filter Corporation, No. VCWPO 1400). They were sterilized by dry heat at 70° for 48 h. After introduction of the cell suspension and sealing, one chamber was inserted into the peritoneal cavity of each of the C57Bl mice (male, 20  $\pm$  2 g body weight) in the experimental groups. Cell suspensions and chambers were kept at 4° throughout the course of an experiment.

Five days later the mice were grafted with skin taken from the ventral surface of male CBA mice. Grafts were inspected 9, 11, 13 and 15 days after grafting and daily thereafter. Signs of rejection were considered to be moistness, oedema, loss of epithelium or scabbing and, in the long-standing grafts, scaling or contraction of the graft to less than a quarter of its original size. Grafts were kept covered with a 'Band-Aid' for 15 days, unless rejected earlier.

The results of nine separate experiments of this type, together with appropriate controls, are presented in Table 1. They indicate that the experimental system used was capable of prolonging allograft survival in a significant number of treated animals. In view of the failure to prolong allograft survival in two of the experimental groups, it would not be possible to state categorically that similar results would not have been obtained had the control groups been larger and more numerous. It seems more likely, however, that the prolongation of allograft survival noted here was caused by a diffusible humoral factor, produced as the result of a reaction by viable rat spleen cells against inactivated mouse lymphoid cells in the diffusion chambers.

Allograft survival was unaffected in a number of treated animals. There are many possible reasons for this. First, it may have been caused by deficiencies in the experimental design. The number of cells in the chambers, the ratio of rat to mouse cells used and the timing of skin grafting in relation to the introduction of the chambers, could all have been less than optimum.

Second, failure to prolong allograft survival may have been, and probably was to a large extent, caused by problems inherent in the use of diffusion chambers. The pores of the membrane frequently become blocked with fibrin; this would certainly compromise the viability of cells in the chamber and at the same time prevent the escape of humoral factors. Very occasionally, cells have leaked from chambers which were defectively sealed. When, however, chambers from animals on which allograft survival had not been prolonged were examined, the two most common findings were infection around and clot formation in the chambers. Infection, which is usually of a low grade, results in encapsulation of the chamber with fibrin, serous fluid, omentum and gut; the contained cells die. Clot formation, which has been previously described by others<sup>1,2</sup>, occurs with unpredictable frequency and results in the formation of a gelatinous clot in which most of the cells are incorporated. Infection and clot formation were rarely found when chambers were examined from animals on which graft survival had been prolonged.

## HAEMATOLOGY

### Nature of Luteinizing Hormone Releasing Factor in Hypophysial Portal Blood

In 1966 Worthington<sup>1</sup> described a method for the collection of hypophysial portal blood from the cut pituitary stalk of rats. This method was used by Fink, Nallar and Worthington<sup>2,3</sup> to demonstrate the presence of luteinizing hormone releasing factor (LRF) in portal blood obtained from rats in proestrus and from rats hypophysectomized at least two weeks before collection. The chief disadvantage of this method of collection of portal blood was that contamination of samples by blood flowing back through pituitary sinusoids and bearing significant quantities of

Fig. 1. Elution profile on 'Sephadex G-25'. 9 ml. portal plasma from nine ovariectomized rats extracted with acid alcohol. Supernatant evaporated, redissolved in 4.5 ml. of distilled water and loaded on a column of 'Sephadex G-25' (fine), 35.5  $\times$  2.5 cm. Eluted with 0.3 molar acetic acid; 5.0 ml. fractions; rate 0.5 ml./min. Fraction I contains substances of molecular weight > 5,000; Fraction II contains substances of molecular weight < 5,000.

Fig. 2. Elution profile on 'Sephadex G-25'. 9 ml. portal plasma from nine animals extracted with acid alcohol. Supernatant evaporated and redissolved in 4.5 ml. distilled water. Loaded on to a column of 'Sephadex G-25' (fine) 35.5  $\times$  2.5 cm; eluted with 0.3 molar acetic acid; 5.0 ml. fractions; rate 0.5 ml./min. Fraction II lyophilized, redissolved in 4.5 ml. distilled water and refractionated on same column. Eluate divided into six fractions and assayed by OAAD method. LRF activity found in shaded region. Note activity in d suggesting adsorption ( $K_d > 1$ ).

anterior pituitary hormones could not be prevented. Thus, because the ovarian ascorbic acid depletion method<sup>4,5</sup> was used to assay the plasma, some of the activity exhibited by portal plasma from animals in proestrus probably resulted from luteinizing hormone (LH).

The exclusion of LH from samples of hypophysial portal plasma has been achieved by use of an unpublished method devised by Dr C. P. Fawcett in which the plasma is extracted with acid alcohol and fractionated on 'Sephadex G-25'. Substances of molecular weight greater than 5,000 are excluded from the gel particles and so, therefore, any trace of LH which remains after extraction appears in the void volume (fraction I, Fig. 1), whereas substances such as LRF, with molecular weights lower than 5,000, are included in the gel particles and appear in fraction II (Fig. 1). This method has been used to demonstrate the presence of LRF in hypophysial portal blood from hypophysectomized and ovariectomized rats, and from rats at various stages of the oestrous cycle<sup>6</sup>.

The aim of the experiments reported here was to use gel filtration to obtain an estimate of the molecular weight of LRF extracted from hypophysial portal blood of rats which had been ovariectomized 3-8 weeks before collection. The ovarian ascorbic acid depletion assay<sup>4,5</sup> was used to determine LRF activity.

The behaviour of LRF when fractionated on 'Sephadex G-25' was investigated first. As is shown in Fig. 2, LRF activity was present in the first four subfractions of fraction II. Because activity persisted beyond the electrolyte region, adsorption played a part in the retention of LRF by the gel. This precluded the use of calibrated columns of 'Sephadex G-25' to estimate the molecular weight of LRF.

It was decided, therefore, to use 'Sephadex G-10', which has an exclusion limit of 700-900, to determine whether the molecular weight of LRF in portal blood was above or below this range. Evidence from studies on LRF in which extracts of hypothalamus and stalk median eminence were used<sup>7</sup> has suggested that this substance is a polypeptide, with a molecular weight of 1,500-2,000. Consequently, it was thought that LRF would be excluded from 'Sephadex G-10'; the results, however, were quite unexpected.

Fig. 3. Elution profile on 'Sephadex G-10'. 4.0 ml. of Fraction II from 'Sephadex G-25' (2 × concentrated) loaded on column of 'Sephadex G-10' 43.0 × 2.5 cm. Eluted with 0.3 molar acetic acid; 5.0 ml. fractions; rate 0.35 ml./min. Eluate divided into five fractions and assayed by OAAD method. LRF activity in shaded region. Note retention of β beyond tyrosine.

Fig. 4. Elution profile on 'Sephadex G-10'. 4.0 ml. of Fraction II (concentrated from 24 ml. of portal plasma) from 'Sephadex G-25' loaded on column of 'Sephadex G-10' 94.0 × 2.5 cm. Eluted with 0.3 molar acetic acid; 5.0 ml. fraction; rate 0.5 ml./min. Eluate divided into eight fractions, aliquots of which were assayed by the OAAD method and by determining release of LH from the anterior pituitary glands of ovariectomized, oestrogen, progesterone blocked rats. LRF activity found in shaded region.

Hypophysial portal plasma was extracted and fractionated on 'Sephadex G-25'. The small molecular weight fraction (II) was lyophilized to dryness, redissolved in distilled water and fractionated on 'Sephadex G-10' (Fig. 3). Activity was found in two regions, α and β, separated by an interval which included the electrolytes. Whereas α was largely excluded from the gel particles, β was markedly adsorbed. This experiment was repeated twice using longer columns of 'Sephadex G-10' (Fig. 4). Similar results were obtained.

In order to exclude the possibility that α and β had caused depletion of ovarian ascorbic acid by direct action on the ovary rather than by the release of LH from the anterior pituitary gland of the test animals, aliquots of fractions from the experiment shown in Fig. 4 were injected intravenously into ovariectomized, oestrogen, progesterone treated rats<sup>8</sup>. Fractions from regions α (a and b) and β (e, f, g and h) caused a significant rise in the level of LH in the plasma of the intermediate animals (assayed by the ovarian ascorbic acid depletion method), whereas fractions c and d from the intervening region had no effect.

These results indicate that the LRF activity of hypophysial portal blood from ovariectomized rats may be caused by two specific substances. It is possible, however, that β is the active molecule and that α consists of a carrier molecule to which β is attached. Dissociation of a proportion of α during extraction and fractionation would then explain the finding of two active substances. The alternative explanation, that α is a polymer of β, must also be considered. The possibility that the activity of these substances was caused by vasopressin or by a non-specific factor introduced during the collection of portal blood has been excluded in previous experiments<sup>9</sup>.

The molecular weight of α probably lies in the range of 900-5,000; however, because of the strong adsorption

of  $\beta$  by 'Sephadex G-10', a valid estimate of the molecular weight of this substance may not be made. The adsorption of  $\beta$  suggests that it probably contains a heterocyclic or aromatic component. Because of the low pH of the eluent and the presence of considerable quantities of electrolytes, it is unlikely that electrostatic forces played a principal part in the adsorption of  $\beta$  by the gel<sup>9</sup>.

It is of interest that recently Fawcett, Reed, Charlton and Harris (personal communication), using anion exchange chromatography and gel filtration in a partially organic medium, found two regions of LRF activity in extracts of hypothalamus.

I thank Professor G. W. Harris for suggesting this project and for advice. I also thank Dr D. B. Hope for criticism. This work was supported in part by the Medical Research Council and the US Air Force.

### Localization of Transferrin in Human and Rat Liver by Fluorescent Antibody Technique

FLUORESCENT antibodies have been used to demonstrate intracellular albumin and fibrinogen in human liver<sup>1</sup>. We have shown the presence of transferrin in normal liver cells of man and rat using anti-transferrin and fluorescein-labelled anti-globulin.

Human transferrin was supplied by Behringwerke AG., and rat transferrin was prepared by the method of Gordon and Louis<sup>2</sup> combining electrophoresis of rat serum on 'Pevikon C870' and chromatography with DEAE 'Sephadex A-50'. Both transferrin samples were found on immunoelectrophoretic analysis to contain small amounts of  $\gamma$ -globulin and were therefore further purified by passage through 'Sephadex G-100'.

Rabbits were injected intramuscularly with 10 mg of transferrin and Freund's complete adjuvant, equally divided between five sites. Booster injections were given with pure transferrin 4 and 8 weeks after the primary injection. Antibody titre was assessed by the tanned sheep cell haemagglutination technique after Stavitsky<sup>3</sup>, by gel diffusion and by immunoelectrophoresis. Potent antisera were collected after the second booster injection; neither antiserum showed absolute specificity to human or rat transferrin, showing the difficulty of preparing wholly pure antigens from serum proteins. For use the antisera were rendered specific by absorption of the anti- $\gamma$ -globulin component.

Rabbit IgG was prepared by separation of 40 per cent ammonium sulphate precipitated rabbit serum on DEAE 'Sephadex A-50', the fraction eluted with 17.5 mmolar phosphate buffer, pH 6.8, and kept for immunization. Sheep anti-rabbit IgG was prepared using the schedule already described. Titre was estimated by the haemagglutination of group A rabbit red cells sensitized with anti-A serum. Sheep anti-rabbit IgG was conjugated after the method of Goldstein, Slizys and Chase<sup>4</sup>. Before conjugation with fluorescein isothiocyanate, the sheep immunoglobulin was prepared in a pure form and after conjugation the fluorochromed protein was fractionated on DEAE 'Sephadex A-50' as described by Goldstein

*et al.*<sup>4</sup>. Conjugate fractions with a fluorescein/protein ratio between 0.4 and  $2.5 \times 10^{-3}$  with a protein concentration of 10 mg/ml. were saved for use. The conjugate was diluted 1:3 for staining.

Human liver was obtained fresh from an operation and was immediately frozen at  $-50^\circ\text{C}$ . Rat tissues were taken fresh when required and directly frozen at  $-35^\circ\text{C}$  on a cryostat chuck. Sections, 2 $\mu$  thick, were cut in a cryostat and the fluorescent staining was performed as an indirect technique on unfixed tissues. The following blanks were set up with all preparations: (1) unstained tissue (autofluorescence); (2) tissue plus sheep anti-rabbit IgG conjugate (non-specific fluorescence); (3) tissue plus rabbit anti-rat serum absorbed with pure rat transferrin followed by conjugate. Slight autofluorescence was seen in the liver capsule, but this was not obtrusive. Non-specific fluorescence was absent. Absorption of the anti-transferrin serum resulted in the loss of the specific staining pattern.

Fig. 1. Fluorescent transferrin cells in human liver. Low power view showing the scattered distribution.

Fig. 2. Fluorescent transferrin cells in human liver. Oil immersion field showing cytoplasmic granularity and absence of nuclear staining.

**Human liver.** Cells exhibiting bright fluorescence and staining specifically for transferrin were seen in all preparations (Figs. 1 and 2). There was a scattered distribution of such cells throughout the liver tissue within the lobule; there seemed to be no special pattern associated with the centrilobular vein or round the periphery of the lobule. A much greater percentage of staining was seen in the parenchymal than in Kupffer cells, and in both fluorescence was cytoplasmic with no nuclear staining. High power examination revealed that the fluorescent parenchymal cytoplasm was granular

Fig. 3. Fluorescent transferrin cells in rat liver. Low power view showing the general distribution comparable with the human liver, but with a diminution in the number of staining cells.

Fig. 4. Fluorescent transferrin cells in rat liver. Oil immersion field showing pan-cytoplasmic fluorescence and absence of nuclear staining.

and that some cells showed only cytoplasmic granules rather than pan-cytoplasmic fluorescence.

**Rat liver.** The pattern of staining was the same in rat liver as in human liver (Figs. 3 and 4), but fewer cells showed fluorescence. The stained cells were evenly distributed throughout the tissues. High power examination (Fig. 4) revealed a close similarity with human liver, that is variability in intensity of fluorescence, no nuclear staining, but obvious cytoplasmic granularity.

These results indicate that the distribution of transferrin in the liver is similar in many ways to that of albumin and fibrinogen. The human and rat livers selected for the investigation of transferrin were considered to be normal, and so the results may be representative for the liver in the steady state. We hope that further experiments aimed at stimulating increased synthesis of transferrin will result in an altered pattern of distribution and this is now being studied.

## Serum Transferrin Polymorphism in the Desert Sheep of the Sudan

SINCE the introduction of starch-gel electrophoresis by Smithies<sup>1</sup>, the intraspecific polymorphisms of several types of iron-binding *B*-globulins (transferrins) in the sera of different species of farm animals have been examined by a number of workers. In sheep the number and frequency of the transferrins have been found to vary from one breed to another: Ashton<sup>2</sup> and Ashton and Ferguson<sup>3</sup> have reported as many as five to seven zones in any one breed. This communication deals with the results of a preliminary investigation of serum transferrin polymorphism in the desert sheep of the Sudan.

In all, 393 samples of blood serum were available for this study. The blood samples were obtained from the sheep as they were being killed at Omdurman abattoir, which receives animals from most of the arid parts of Northern Sudan.

Table 1. COMPARISONS OF THE TRANSFERRIN ZONES IN DESERT SHEEP WITH SHEEP REFERENCE SERA OBTAINED FROM WAGENINGEN

											G	

Starch-gel electrophoresis using a *tris*-discontinuous buffer system was used to identify the serum transferrin types. Seven transferrin zones, each represented by one densely stained and another faintly stained, were found to occur in serum from desert sheep of the Sudan. This number of observed zones is similar to that reported by Ashton and Ferguson<sup>2</sup> in Australian Merino sheep. Fig. 1 shows the five out of the observed seven transferrin zones. Starting from the fastest zone the following nomenclature was assigned to the seven observed zones: TfA, TfB, TfC, TfD, TfE, TfF and TfG. To overcome the confusion already existing in the nomenclature of sheep transferrins, reference sera coded according to the recent nomenclature approved at the tenth (Paris) conference of the European Society for Animal Blood Group Research were obtained with the kind co-operation of Dr C. C. Oosterlee, of Wageningen, The Netherlands. Table 1 shows a comparison between the transferrin types identified in the desert sheep and those obtained from Wageningen. Figs. 2a and b show some of these comparisons.

Fig. 1. Desert sheep serum transferrin types after starch-gel electrophoresis.

Fig. 2. Sheep transferrin types after starch-gel electrophoresis. Transferrin types GC, BM and DP are the Wageningen standards.

The results in Table 1 show that the fastest zone in the desert sheep corresponds with the second fastest in the Wageningen standards. Furthermore, the results show that there is an extra zone in the desert sheep which lies between the Wageningen TFG and TFB transferrin zone. If this new zone is called TFB' and the others are re-coded according to the Paris nomenclature the transferrin zones in the desert sheep of the Sudan would then correspond to TFA, TFB', TFB, TFC, TFM, TFE and TFP. Assuming that each zone is produced by the action of one gene, a maximum of twenty-eight phenotypic combinations would be expected from an allelic series of seven genes. Table 2 gives the calculated frequency of the seven co-dominant transferrin alleles. It can be seen from Table 2 that the allele TFB was the most frequent in

desert sheep, followed by TFC. TFP was the least frequent. Table 3 gives the actual and expected frequencies of the twenty-eight possible transferrin phenotypes. As chi-square tests cannot be carried out in those classes represented by less than five individuals, adjusted chi-square value was calculated after pooling or merging the phenotypic classes containing less than five individuals with larger ones. The adjusted chi-square value is given at the foot of Table 3 and is significant, suggesting that random mating was not necessarily operating. This may suggest that some phenotypes may have certain selective advantage in certain environments.

A general survey of the serum transferrin types, sodium and potassium levels in the blood of desert sheep from different geographical regions and from other Sudanese types of sheep is under way.

### Post-heparin Lipolytic Activity and Blood Platelets

THERE have been several reports indicating a possible interrelationship between plasma lipoprotein lipase activity and blood platelets. Mitchell<sup>1</sup> and Gardikas *et al.*<sup>2</sup>, using changes in the optical density of plasma as indicators of lipolytic activity, have reported an inhibition of lipoprotein lipase activity by platelets. The presence of platelets contributes materially to plasma turbidity, however, and the changes in optical density, particularly proportionate changes, may not be an accurate measure of lipase activity. Hollett and Nestel<sup>3</sup> have shown that the clearing activity after administration of heparin, as measured by changes in optical density, and lipolytic activity, as determined by glycerol production, do not necessarily parallel each other. More recent results indicate that the lipoprotein lipase activity and "stickiness" of blood platelets are both altered in human cardiovascular disease<sup>4</sup>. We therefore decided to reinvestigate the relationship between lipoprotein lipase and blood platelets using heparin as an inducer and the release of free fatty acids (FFA) as a measure of the lipolytic activity.

Non-fasting adult Sprague-Dawley rats of either sex were injected intravenously either with 10 mg heparin/kg body weight or with an equivalent volume of saline. Blood samples were drawn by heart puncture into a heparinized syringe 10 min after the injection and divided into two aliquots. One aliquot was centrifuged at 4°C and 160g for 10 min to obtain platelet-rich plasma, the other part at 4°C and 4,000g for a similar length of time to produce platelet-poor plasma. The plasma samples were then incubated at 37°C for 1 h and the FFA concentrations determined by the method of Dole<sup>5</sup>. In other studies, 1 ml. portions of platelet-rich plasma taken after administration of heparin were centrifuged at 4°C and 4,000g

Table 1. EFFECT OF POST-HEPARIN BLOOD PLATELETS ON RELEASE OF PLASMA FREE FATTY ACIDS

Treatment	No. of rats	Plasma		Difference (μequiv./l.)
		Platelet-poor (μequiv./l.)	Platelet-rich (μequiv./l.)	
Heparin	34	944	1,085	141 ± 30*
Control	12	458	478	16 ± 38
Heparin	15	604	1,903†	1,299 ± 34
Heparin	7	589	798‡	209 ± 34
Control	3	463	525§	62

The heparin blood samples were obtained 10 min after intravenous injection of 10 mg heparin/kg body weight. All plasma samples were incubated at 37°C for 1 h.

\* Mean ± standard error.

† Post-heparin platelets resuspended in control plasma.

‡ Post-heparin platelets washed with saline and resuspended in control plasma.

§ Control platelets resuspended in control plasma.

for 10 min; the resulting platelet buttons were then resuspended in 1 ml. platelet-poor control plasma and incubated at 37°C for 1 h. In an additional series, platelet buttons from 1 ml. portions of post-heparin platelet-rich plasma were washed in 2 ml. of physiological saline, recentrifuged at 4,000*g*, resuspended in 1 ml. of control plasma and again incubated at 37°C for 1 h. In the control series, platelet buttons from control plasma were resuspended in control plasma and processed as described.

On incubation, the post-heparin platelet-rich plasma released significantly more FFA than the corresponding platelet-poor samples ( $P < 0.01$ , paired comparison, Table 1). No such differences were observed with platelet-rich and platelet-poor control plasma. Post-heparin platelets incubated in control plasma released 1,299  $\mu$ equiv. FFA per litre of plasma; washing the platelets with saline reduced the FFA release to 209  $\mu$ equiv./l. Incubation of control platelets in control plasma (Table 1) or in post-heparin plasma produced a negligible release of FFA. Neither control nor post-heparin erythrocytes or leucocytes showed any consistent enhancement of lipolysis<sup>6</sup>.

It would seem, therefore, that the presence of post-heparin platelets in plasma can enhance the post-heparin lipolytic activity. The mechanism of this effect is not clear at present; however, the observation that the lipolytic activity can be reduced by washing the platelets suggests that the enzyme (or enzymes) involved is absorbed at the cell surface. A possible correlation between the amount of lipolytic activity on the platelet surface and platelet "stickiness" remains to be investigated.

### Effect of Heparin on Mixed Lymphocyte Cultures

Mixed lymphocyte culture may well offer a valuable assay of histocompatibility and it has been suggested that it can be used in donor selection for allotransplantation<sup>1,2</sup>. Goldsmith<sup>3</sup>, however, finds that this technique produces variable results when it is repeated with cells from the same individuals. Bach and Voynow<sup>4</sup> have also reported contradictory results on consecutive days. One reason for the lack of reproducibility may be the method of collecting samples of blood.

Taylor and Culling<sup>5</sup> have recently demonstrated that heparin inhibits the cytopathic effect of immune spleen cells in fibroblasts. Previously Johnson and Bencze<sup>6</sup> had shown that the lupus erythematosus cell phenomenon

Fig. 1. The effect of serial dilutions of heparin on mixed lymphocyte cultures (●) and phytohaemagglutinin-stimulated lymphocytes (○). Depression of transformation is expressed as a percentage reduction of each untreated control result.

*in vitro* is suppressed by heparin, which is a commonly used laboratory anticoagulant, often used in the preparation of lymphocyte suspensions<sup>1,4,7,8</sup>. An investigation of the effect of heparin on mixed lymphocyte cultures was therefore performed.

Lymphocytes were isolated from defibrinated peripheral venous blood of healthy unrelated volunteers using the technique described by Coulson and Chalmers<sup>9</sup>. Mixed lymphocyte cultures were set up in medium 199 containing 25 per cent normal human serum. The cell concentrations were adjusted to 10<sup>6</sup> lymphocytes/ml. Control cultures of single donor cells were also established. Crystalline heparin (Boots, 167 U/mg) was made up in the culture medium in serial ten-fold dilutions. Single donor cultures were treated with 2.5 per cent phytohaemagglutinin and incubated with and without heparin. All cultures were left in inclined glass test-tubes for 72 h at 37°C. Smears of each culture were made, air dried, fixed in methanol and stained by the Jenner-Giemsa method. The morphologically blastic and mitotic cells in each culture were counted. The percentage of transformed cells in each culture without heparin was regarded as the control and depression of lymphocyte transformation was expressed as a percentage reduction of this figure for each experiment. Lymphocytes from eighteen donors were used and the results obtained are expressed in Fig. 1.

The results demonstrate that at a concentration of 100 U/ml. and more heparin was profoundly toxic to lymphocytes. There was gross distortion and fragmentation of all nucleated cells in the cultures. At lower concentrations lymphocyte transformation was depressed in the absence of morphological signs of toxicity. This depression occurred at concentrations as low as 0.1 U/ml. Heparin, however, produced very little reduction in transformation induced by phytohaemagglutinin, even at 10 U/ml., a concentration at which there was considerable depression in the mixed cultures. Control cultures of single donor lymphocytes all revealed less than 5 per cent blastic transformation.

The fact that heparin suppressed lymphocyte transformation caused by allogeneic cells but not that

caused by phytohaemagglutinin indicates that the "transformability" of the lymphocytes was not affected. The inhibitory effect of heparin must therefore occur on the afferent arm of the transformation process, possibly suppressing antigen detection. Taylor and Culling<sup>6</sup> have explained the inhibitory effect of heparin on immune spleen cells as possibly involving modification of the cell surface. Heparin is a powerfully electro-negative substance and has been shown to coat cells *in vitro*<sup>10</sup>. By increasing the already high negative surface charge of the normal lymphocyte<sup>11</sup> it would increase intercellular electrostatic repulsion and could therefore act by inhibiting cell contact. Weiss has speculated<sup>12</sup> that surface charge may regulate the "magnitude of potential energy barriers to contact" between cells. Failure of lymphocytes to make contact with cells containing alloantigens could therefore account for the reduction in the formation of blast cells caused by heparin.

I suggest, therefore, that the variable results from mixed lymphocyte cultures can be explained by variations in the concentration of heparin. Heparin should thus be avoided in the preparation of lymphocyte cultures.

This work was carried out while I was a recipient of a Saltwell scholarship from the Royal College of Physicians, London.

## BIOCHEMISTRY

### Action of Ultra-violet Light on Soluble Collagens

It has been shown<sup>1</sup> that rat tail tendon becomes less soluble after exposure to short wave ultra-violet light and that the amount of soluble collagen in mouse skin was decreased after irradiation<sup>2</sup>. Fujimori<sup>3</sup>, working with acetic acid solutions of calf skin collagen, recently showed that irradiation resulted in the acquirement of ability to fluoresce in long wave ultra-violet light. These changes in properties have been ascribed to the formation of cross-links from the aromatic side-chains of phenylalanine and tyrosine<sup>3,4</sup>. Working with suspensions of acid-soluble and neutral salt-soluble collagens from rat skin we have also found that short wave ultra-violet light does produce fluorescence, and we have sought to measure the fluorescence quantitatively and correlate this with changes of solubility and shrinkage temperature after different periods of irradiation.

Purified collagens soluble in acid and neutral salts were prepared from the skin of 6 week old rats by the method of Jackson<sup>5</sup> as modified by Gross and Kirk<sup>6</sup>. Solutions of these collagens were stored at 4° C, the former in 0.1 molar acetic acid and the latter in 0.14 molar sodium chloride, containing 0.02 molar phosphate, pH 7.2. The skin remaining after extraction was treated by incubation

with trypsin in *tris* buffer, pH 8.2, to remove non-collagen protein, followed by treatment with chloroform to remove fat, followed by two further trypsin treatments. The material ("extracted rat skin collagen") was then washed with water and autoclaved in water for 2 h at 120° C and the solution separated from the insoluble residue of hair and other non-collagen. This solution suitably diluted was used as reference in fluorescence measurements. Hydroxyproline<sup>7</sup> and nitrogen<sup>8</sup> analyses were carried out on this solution and on autoclaved aqueous solutions of the soluble collagens. The hydroxyproline nitrogen was 7.5, 8.3 and 7.9 per cent of the total nitrogen for the extracted rat skin collagen, acid-soluble and neutral salt-soluble collagens, respectively.

Acid-soluble collagen was precipitated from 0.1 molar acetic acid solution by neutralization to pH 7-7.5 and incubation at 37° C. The fibrous precipitate was washed with water. Freshly prepared aqueous suspensions fluoresced relatively weakly compared with the extracted rat skin but acquired increased fluorescence after standing for some days or weeks. This increase with time, measured against a suitable standard, varied from batch to batch and appeared to require daylight. We then turned our attention to the production of fluorescence by irradiation with ultra-violet light. About 5 ml. of aqueous collagen suspension containing about 10 mg/ml. was placed in a crucible, stirred magnetically and exposed to light from a 'Chromatolite' lamp (Englehard Hanovia, Ltd.) with a maximum emission of 254 mμ. The base of the crucible was 4 cm from the lamp. Samples (about 0.5 ml.) were withdrawn at intervals. From these samples a small amount of fibres was removed, suspended in 0.14 molar sodium chloride for *T<sub>s</sub>* measurement in capillary tubes<sup>9</sup>. Fibres teased out from the skin of rats 6 weeks old (native collagen) served as reference material for *T<sub>s</sub>* measurements. The remaining suspension was made to 2-3 ml. with water, sealed and autoclaved for 2 h at 120° C. The resulting solutions (containing the equivalent of 1-2 mg collagen/ml.) were used to measure fluorescence and hydroxyproline content. Fluorescence at maximum emission was measured in the Locarte fluorimeter, Mark 4. The exciting light in this apparatus came from a mercury vapour lamp through a Wood glass filter, the fluorescent light passing through a monochromator. The reference material was a solution of extracted rat skin collagen of known hydroxyproline content as already mentioned. The results are shown in Table 1. Fluorescence figures are adjusted for equal hydroxyproline concentrations.

A second irradiation experiment was carried out to compare neutral salt-soluble with acid-soluble collagen. In this case the same conditions as previously could not be used, because the neutral salt-soluble collagen became soluble on washing with water. The neutral salt-soluble collagen was precipitated from its salt solution by incubation at 37° C, part retained for autoclaving in water and part (about 5 ml. containing about 1 mg collagen/ml.) was irradiated. After irradiation for 1.5 h the collagen was no longer soluble in water and the irradiation was thereafter continued on the collagen suspended in water. There was not sufficient neutral salt-soluble collagen available to allow periodic sampling for fluorescence and hydroxyproline as in the first experiment, so these

Fluorescence maxima (m $\mu$ )	405	410	400	425	415

estimations were carried out before and at the end of the irradiation period. A similar amount of acid-soluble collagen, freshly prepared from acetic acid solution, was irradiated under the same conditions. In fluorescence measurements of samples before irradiation, the salt solution was replaced by water. The results of this experiment are given in Table 2.

The spectral characteristics of autoclaved solutions of irradiated and non-irradiated soluble collagens and of the extracted rat skin collagen were measured in the Aminco-Bowman spectrofluorimeter (we thank Dr J. R. Daley, West London Hospital, for the use of this apparatus). The results (uncorrected) are given in Table 3.

The results show that short wave ultra-violet light has a marked effect on the properties of the soluble collagens. Irradiation causes a decrease in solubility and an increase in  $T_s$  and fluorescence. These effects are noticeable after only a short exposure, and are consistent with the formation of new cross-links and increased hydrogen bonding. The fluorescence of acid-soluble collagen in suspension increases with time of irradiation (Table 1), as Fujimori<sup>3</sup> also found for collagen in solution, but the  $T_s$  tends to level off with time, approaching that of the native collagen. We have also found in other experiments, however, that prolonged irradiation of acid-soluble collagen suspension resulted in a slight fall in both fluorescence and  $T_s$ , which would be consistent with the breakage of bonds by ultra-violet light of sufficient energy<sup>4,10</sup>. Comparison of the results for acid-soluble collagen in Tables 1 and 2 indicates that initial conditions may have some influence on the final effects. In the former the  $T_s$  ranges are somewhat greater than those of the latter. The results in Table 2 show some differences between the behaviour of the two types of collagen towards ultra-violet light. Neutral salt-soluble collagen attains its maximum  $T_s$  after 1.5 h of irradiation, whereas the acid-soluble collagen requires a longer exposure. The final  $T_s$  of neutral salt-soluble collagen is the same as that of the native collagen, whereas that of the acid-soluble collagen is somewhat lower. On the other hand, the relative increase of fluorescence is much greater for acid-soluble collagen than for neutral salt-soluble collagen. The relatively high initial fluorescence of neutral salt-soluble collagen could be due to traces of contamination, but the relatively small increase of fluorescence with irradiation is almost certainly a property of the collagen itself.

If fluorescence is due to a certain type of covalent cross-link (and the spectral results in Table 3 suggest a similarity between such cross-links in irradiated and non-irradiated collagens) then it appears that this type of linkage is not the only factor in determining high  $T_s$  and low solubility. This conclusion is supported by the relatively high fluor-

escence of extracted rat skin collagen, which has a low shrinkage temperature. Prolonged exposure to acetic acid in the extraction process has evidently brought about extensive disruption of hydrogen bonds but not of those bonds responsible for fluorescence. Fluorescence cross-linking may, however, play a part in the final stabilizing of the structure of native collagen as previous observations<sup>9,11</sup> suggest.

### Effect of Rotenone on the Alcohol Dehydrogenase of Yeast Mitochondria

CHANCE<sup>1</sup> applied the crossover theorem to a study of intact yeast cells, and reported an apparent crossover point (or phosphorylation site) between pyridine nucleotide and flavoprotein (site I), between cytochromes *b* and *c* (site II) and between cytochrome *c* and cytochrome oxidase (site III). These observations led to the expectation that intact isolated yeast mitochondria would exhibit no anomalies with respect to their phosphorylation capacity. More recently Mattoon and Sherman<sup>2</sup> used loosely coupled yeast mitochondria and obtained indirect results supporting the observations of Chance.

Ohnishi *et al.*<sup>3</sup>, using a preparation of tightly coupled yeast mitochondria, and Schatz *et al.*<sup>4</sup>, using a yeast respiratory particle preparation, however, were unable to

Fig. 1. Effect of rotenone on the respiration of rat liver and yeast mitochondria. In addition to rotenone, the 3 ml. polarographic reaction chamber contained: (I) 1.5 mg yeast mitochondrial protein, 133 mmolar ethanol, 25 mmolar semicarbazide, 42  $\mu$ molar dinitrophenol, 0.6 molar mannitol, 10 mmolar sodium phosphate buffer, pH 6.5; (II) 0.75 mg yeast mitochondrial protein, 16 mmolar succinate, 42  $\mu$ molar dinitrophenol, mannitol and buffer as in (I); (III) 10 mg rat liver mitochondrial protein, 33  $\mu$ molar  $\beta$ -OH-butyrate, 8  $\mu$ molar dinitrophenol, 0.25 molar mannitol, 10 mmolar potassium chloride, 10 mmolar *tris* buffer, 5 mmolar potassium phosphate and 0.2 mmolar EDTA, pH 7.4. The temperature was 25° C.

Fig. 2. Representative polarographic trace illustrating the effect of rotenone, malonate and antimycin A on rapidly respiring (state 3) yeast mitochondria. The conditions were similar to those described in Fig. 1. The final concentrations are given below the polarographic trace while the rates in  $\mu$ molar oxygen/min are indicated above the trace. Excess rapidly respiring yeast cells are added to obtain a zero oxygen calibration point.

obtain ratios of phosphorus : oxygen greater than 2 with pyridine nucleotide-linked substrates. These observations, together with the fact that isolated mitochondria are not sensitive to rotenone, seem to lead to the conclusion that yeast mitochondria exhibit a fundamental difference in their respiratory processes when compared with other types of mitochondria.

While testing the effect of rotenone on tightly coupled yeast mitochondria in our laboratory, we increased the rotenone concentrations to values exceeding those generally observed to be effective with mammalian mitochondria. In these conditions rotenone exhibited a pronounced inhibition of the uptake of oxygen with ethanol-supported respiration, although the same concentrations of rotenone had little or no effect on the rate of succinate or pyruvate plus malate oxidation. Further investigation of this phenomenon has revealed that rotenone appears to exert its effect through a direct action on the yeast mitochondrial alcohol dehydrogenase.

Yeast mitochondria were prepared either from baker's yeast purchased from the Federal Yeast Co., Baltimore, Maryland, or from a laboratory strain of *S. cerevisiae* (strain D-261) according to a modification of the method of Mattoon and Balcaavage<sup>5</sup>. This method consists of a gentle grinding of the yeast in a 0.6 molar mannitol medium containing 0.2 per cent bovine serum albumin (Sigma fraction V), and  $10^{-4}$  molar EDTA, using an Eppenbach 'Micro-mill', followed by careful separation of the intact heavy mitochondria from other cellular material by differential centrifugation. The resulting preparation exhibits respiratory control ratios of 1.5–3.5 with 16 mmolar succinate as substrate and 1.5–2.5 with 133 mmolar ethanol as substrate. The ratios of phosphorus : oxygen with either of these substrates have not been observed to exceed 2.0.

Crystalline yeast alcohol dehydrogenase (ADH) (Calbiochem, Los Angeles) was assayed in conditions similar to those described by Kägi and Vallee<sup>6</sup>. The rate of ADH reaction was followed as the increase in absorbancy at 340 m $\mu$  (NAD $\rightarrow$ NADH). Mitochondrial respiration was followed using a 'Teflon' covered Clark oxygen electrode polarized at  $-0.8$  V, immersed in a 3.0 ml. semi-closed reaction vessel. Rotenone (K and K Laboratories, Inc., Plainview, N.Y.) was prepared as a stock solution of  $1 \times 10^{-3}$  moles/l. in methanol. Two 80  $\mu$ l. portions of this solution were added to the reaction mixtures to achieve the final concentrations indicated. All other chemicals used were of reagent grade. Rat liver mitochondria were prepared according to the method of Schneider<sup>7</sup> and assayed in the medium described by Chance and Hollunger<sup>8</sup>.

In Fig. 1 the effect of rotenone on the respiration of yeast mitochondria during the catalysis of ethanol oxidation (I) is compared with its effect on rat liver mitochondria during  $\beta$ -hydroxybutyrate oxidation (III). It is apparent that the observed inhibitions differ both qualitatively and quantitatively. With rat liver mitochondria inhibition by rotenone occurs at the concentrations described by Ernster *et al.*<sup>9</sup> and approaches 100 per cent inhibition. The inhibition of yeast mitochondria during ethanol respiration requires much higher concentrations of rotenone, and an inhibition exceeding 75 per cent has not been observed. Curve II of the same figure illustrates a small effect of high rotenone concentrations on yeast mitochondria catalysing succinate oxidation.

The residual ethanol respiration is insensitive to malonate (even at concentrations as great as 45 mmoles/l.) but is completely blocked by antimycin A as demonstrated by the polarographic trace reproduced in Fig. 2. Because the residual respiration (15.4  $\mu$ molar oxygen/min) exceeds the endogenous respiration (1.7  $\mu$ molar oxygen/min) and is insensitive to malonate, it would seem that the residual respiration must be supported by ethanol oxidation, thus indicating an incomplete inhibition of this process.

Because pyruvate plus malate or isocitrate oxidation was not inhibited by similar concentrations of rotenone, it can be concluded that the inhibition of ethanol oxidation probably does not occur at the level of the respiratory chain. Control experiments showed that methanol alone had essentially no effect on mitochondrial respiration.

Crystalline yeast ADH was then examined for its sensitivity to inhibition by rotenone, and as shown in Fig. 3 the crystalline enzyme exhibits behaviour qualitatively similar to that demonstrated by the enzyme *in situ*; that is, maximum inhibition of only 60 per cent. Kinetic analysis of the rotenone inhibition, as presented in Fig. 4, is consistent with the hypothesis that it is of the mixed type with respect to both NAD and ethanol.

These results thus extend the known physiological effects of rotenone to include a site of attack other than site I within the electron transport chain. Because yeast ADH is at least in part associated with the isolated mitochondria<sup>3,5,10</sup>, it is conceivable that the effect described here may be an example of a more general effect of rotenone on other mitochondrial dehydrogenases. Alternatively, the effect of rotenone on yeast may be specifically associated with ADH and as such may be a useful tool in future studies on the *in vivo* function of this enzyme.

Fig. 3. Effect of rotenone on commercial crystalline yeast alcohol dehydrogenase. The 3 ml. cuvettes contained: 2.6 ml. pyrophosphate buffer (0.115 moles/l.), pH 8.5; 0.15 ml. 50 per cent ethanol; 0.1 ml. NAD (0.03 moles/l.) and 0.1 ml. methanol or rotenone in methanol to achieve the desired final rotenone concentration. The reactions were started by adding 50  $\mu$ l. of an enzyme solution ( $A_{340} = 0.090$ ) to the cuvette and followed, using a Zeiss spectrophotometer attached to a Sargent strip chart recorder, as the increase in absorbancy at 340 m $\mu$ .

Fig. 4. Lineweaver-Burk analysis of the effect of rotenone on the affinity of yeast alcohol dehydrogenase for NAD and ethanol. The conditions are similar to those described for Fig. 3. O, Substrate dependency curve obtained in the presence of methanol alone.  $\Delta$ , Substrate dependency curve in the presence of  $3 \times 10^{-4}$  molar rotenone.

This investigation was supported in part by a Public Health training grant and a Public Research grant from the US National Institutes of Health.

### Caesium Chloride in the Preparation of Membrane Fractions from Human Cerebral Tissue

THE standard procedure for the isolation of myelin and other membrane fractions involves differential and density gradient centrifugation in sucrose solutions. Two bands of myelin, light and heavy<sup>1</sup> or small and large<sup>2</sup>, and many bands of microsomes<sup>3</sup> have been obtained by these techniques when applied to cerebral tissues, and a similar multiplicity of bands has been noted with the use of 'Ficol' gradients<sup>4</sup>. One explanation may be that the membranes exist as vesicles, which are impermeable to sucrose, and thus are separated by buoyant density rather than matrix density<sup>5</sup>. The two bands of myelin obtained show an almost identical lipid composition<sup>6</sup>.

Meselson *et al.*<sup>7</sup> used caesium chloride for the separation and the molecular weight determination of nucleic acids. Caesium chloride should be permeable to membranes existing in vesicular form, and so the technique has been applied to cerebral tissues to prepare purified myelin and microsomes, and the preliminary results of this work are reported here.

Cortex and white matter from three apparently normal human brains were each homogenized (10 per cent w/v) in 0.32 molar sucrose; myelin was prepared from the white matter and microsomes from the cortex. The white matter homogenate after an initial centrifugation at 1,000g was adjusted to 0.25 molar sucrose and layered on to 15 per cent caesium chloride (1 : 10), centrifuged in an MSE refrigerated centrifuge at 4°C in a swing-out rotor for 18 h at 100,000g. The single myelin band at the top was removed and extracted in chloroform-methanol (1 : 1).

The cortex homogenate was centrifuged at 17,500g for 1 h and the supernatant centrifuged at 100,000g in a small angle head for 1 h. The crude microsomal pellet was taken up in 15 per cent caesium chloride and centrifuged at 100,000g in the swing out head for 18 h, when the microsomal pellet was removed and extracted with chloroform-methanol (1 : 1). Dr W. G. P. Mair examined both preparations by electron microscopy and these were either pure myelin of characteristic appearance or microsomes respectively (Fig. 1).

Thin layer chromatography was performed as previously<sup>8</sup>, using as solvent either chloroform, methanol, formic acid and water (70 : 30 : 7 : 3) for phospholipids or chloroform, methanol and water (14 : 6 : 1) for sphingolipids. The phosphorus content of each band, after visualization by spraying with 50 per cent sulphuric acid and subsequent charring, was estimated with recovery of total phosphorus from the plate of between 95 per cent and 98 per cent. Sphingosine was estimated from each sphingolipid band as seen after spraying with 0.2 per cent (w/v) di-chlorofluorescence in 95 per cent ethanol containing 0.02 per cent (w/v) butylated hydroxy toluene with a recovery of 90 per cent to 95 per cent.

Table 1. PHOSPHOLIPIDS IN HUMAN MYELIN AND MICROSOSES (AS PERCENTAGE OF TOTAL PHOSPHORUS)

	Myelin		Microsomes	
	Caesium	Sucrose	Caesium	Sucrose
			"Standard"	"Heavy"
Cardiolipin and phosphatidic acid	0.5	3.0	0	1.0
Phosphatidyl ethanolamine	38.0	38.0	28.8	30.0
Phosphatidyl serine	17.7	16.5	11.2	9.0
Phosphatidyl choline	22.8	19.0	44.6	38.0
Monophosphoinositide	0.5	1.5	0	4.0
Sphingomyelin	20.5	20.0	15.2	13.0

Results from duplicates from each of three brains.

The results of the phospholipid analyses for both myelin and microsomes are shown in Table 1 and the results compared with similar estimations using standard procedures involving sucrose gradients.

The distributions of phospholipids in myelin are comparable by both techniques. It can be mentioned that

Fig. 1. Electron microscopy of microsomal pellet prepared with caesium chloride. ( $\times 30,000$ .)

Fig. 2. Thin layer chromatogram to show gangliosides of lipid extract from microsomes. The solvent was chloroform, methanol and 10 per cent aqueous ammonia (60:35:5); the spray was resorcinol reagent<sup>8</sup>.

from the determinations already carried out the ratios of the sphingosine of cerebroside, sulphatide, sphingomyelin and ganglioside in the microsomal preparations are as 1:0.3:1.5:0.6 and that gangliosides are present in microsomes but not in myelin (Fig. 2). The myelin results agree well with the figures given by Eichberg *et al.*<sup>2</sup> and by Cuzner *et al.*<sup>9</sup>. A single pure microsomal preparation results from the use of caesium chloride as compared with a number that can be obtained when using sucrose, and the phosphorus containing compounds in this one preparation show a pattern very similar to that of "standard" microsomes as prepared from sucrose.

The simplicity of the procedure is such that it can be readily applied to a wide range of pathological material and both this and the distribution of the sphingolipids in myelin and microsomes is at present being carried out.

### Changes of Gamma-aminobutyric Acid, Glutamic Acid and Aspartic Acid in Various Brain Structures of Cats deprived of Paradoxical Sleep

KNOWLEDGE of the role of free amino-acids in the activity of the central nervous system (CNS) and in the basic neural processes of excitation and inhibition has accumu-

lated over a number of years. The pool of free amino-acids in the brain is the source from which amino-acids liberated by the breakdown of proteins are returned<sup>1</sup>. The brain has the highest concentration of glutamic acid, gamma-aminobutyric acid (GABA) and aspartic acid, and these compounds do not occur to any significant extent in the other tissues of mammals. GABA especially occurs only in the CNS of mammalian organisms, and it has been shown that this substance has characteristic physiological effects on the CNS (ref. 2). In nervous tissue, as in other organs, the carbon skeleton of non-essential amino-acids is derived ultimately from glucose by way of the citric acid cycle. Active brain transaminases catalyse the reversible amination and deamination of essential and non-essential amino-acids<sup>3</sup>.

Studies on sleep have revealed clearly the metabolic and enzyme nature of the mechanism of sleep, and especially its paradoxical phase (PS)<sup>4</sup>. Our previous investigations showed that the exogenous and endogenous increase in the amount of GABA in the CNS vigorously suppresses the paradoxical sleep of cats deprived of paradoxical sleep but has no influence on slow sleep<sup>5</sup>. The amino-acid content of the CNS reflects its state and deprivation of paradoxical sleep causes a selective accumulation of paradoxical sleep in the recuperative period, and it seemed interesting to investigate the changes in the amounts of GABA, glutamic acid and aspartic acid in different brain structures, with the object of finding how the general and regional metabolism of these amino-acids in the CNS is related to the mechanisms of paradoxical sleep.

The experiments were carried out on adult cats, which had been deprived of paradoxical sleep according to the technique devised by Jouvet<sup>6</sup>. The animals were decapitated and their heads quickly placed in liquid air. Certain brain structures were extracted from the frozen tissue in a cool chamber and then measured and homogenized in 80 per cent ethyl alcohol. This homogenate was centrifuged at 6,000 r.p.m. After this, supernatants were separated and chloroform added to precipitate proteins. The upper layer of water and alcohol evaporated to dryness. Later, the dry residues were dissolved in 0.1 normal hydrochloric acid (1 ml./g of fresh tissue). All amino-acids were separated by two-dimensional ascending paper chromatography and quantitative analyses were carried out by ultra-violet spectrophotometry at 505 mμ (ref. 7). For each series of experiments standards were prepared from pure amino-acids in hydrochloric acid.

The results of the experiments (Fig. 1) show that in control animals the highest concentrations of GABA occur in the superior and inferior colliculi and in the caudate nucleus and that significantly lower concentrations of GABA occur in the cortex, midbrain reticular formation and thalamus. The concentration of glutamic acid was highest in the caudate nucleus and the thalamus, lower in the frontal cortex, reticular formation and occipital cortex and lowest in the colliculi. The concentrations of aspartic acid in the various cortical and sub-cortical regions of control animals were very similar, but in the thalamus the concentration was slightly higher. The quantities of these amino-acids in animals deprived of paradoxical sleep undergo changes which are primarily regional in character. The largest changes in animals deprived of paradoxical sleep occur in the concentrations of GABA, which show highly significant increases in the reticular formation (39.4 per cent;  $P < 0.01$ ), the thalamus (26.2 per cent;  $P < 0.01$ ), the frontal cortex (15 per cent;  $P < 0.01$ ), and decreases in the colliculi (29.1 per cent;  $P < 0.01$ ) and the caudate nucleus (21.9 per cent;  $P < 0.01$ ). The concentration of GABA decreased in the occipital cortex, but the decrease was not significant (10.9 per cent;  $P > 0.05$ ). The concentration of aspartic acid increased significantly in animals deprived of paradoxical sleep in the thalamus (29.2 per cent;

Fig. 1. Changes of amino-acids. □, Normal; ■, deprivation.

$P < 0.01$ ), the frontal cortex (18.3 per cent;  $P < 0.01$ ), the reticular formation (16.1 per cent;  $P < 0.01$ ), and decreased in the caudate nucleus (26.0 per cent;  $P < 0.01$ ). The changes in the occipital cortex and the colliculi were not statistically significant. Glutamic acid undergoes less change than the other two amino-acids in the experimental conditions used here and the changes in its concentration are not significant, apart from the slight increase in the thalamus (15.3 per cent;  $P < 0.01$ ) in animals deprived of paradoxical sleep.

The results obtained show that the changes in the concentrations of the amino-acids in animals deprived of paradoxical sleep have a high regional specificity which points not only to a specificity of metabolism but also to the functional importance of different regions in paradoxical sleep. We can speculate that the decrease in the concentrations of GABA and aspartic acid, especially in the caudate nucleus—a structure known to exert inactivating influences (electrographic and behavioural) on higher nervous functions<sup>8</sup>—might implicate this structure in the mechanism of paradoxical sleep, depending on the metabolism of these two amino-acids. It is necessary, however, to point out that glutamic acid decarboxylase is very susceptible to the action of its inhibitors in the caudate nucleus<sup>9</sup>. The absence of reciprocal parallelism in the quantitative changes in the concentrations of GABA, glutamic acid and aspartic acid indicates that these amino-acids, which are specially required in the metabolism of various brain structures, do not always follow known metabolic pathways<sup>10</sup>. It is possible that under special conditions GABA, glutamic acid and aspartic acid are transformed into new compounds or are utilized more effectively in the citric acid cycle<sup>11</sup>.

### A 3-Amino-3,6-dideoxyhexose from the Lipopolysaccharide of *Escherichia coli* 071

For a long time fungi were the only known source of naturally occurring 3-amino-3,6-dideoxyhexoses<sup>1</sup>. It was only in 1965 that a representative of this group of amino sugars was reported to be present also in bacteria by Ashwell *et al.*<sup>2</sup>, who isolated 3-amino-3,6-dideoxy-D-galactose from a phenol soluble lipopolysaccharide of *Xanthomonas campestris*. Later 3-amino-3,6-dideoxy-D-galactose was also isolated from the lipopolysaccharides of several *Escherichia coli* strains (unpublished work of Jann, Jann and Müller-Seitz). Recently, a 3-amino-3,6-dideoxyhexose was found in a glycoprotein complex of *Citrobacter freundii*<sup>3</sup>. In the lipopolysaccharides of *Salmonella* group M a 3-amino-3,6-dideoxyhexose was detected (Lüderitz, O., private communication). This communication concerns the isolation of a 3-amino-3,6-dideoxyhexose from the lipopolysaccharide of *E. coli* 071 and its tentative identification as 3-amino-3,6-dideoxyglucose.

Acetone dried cells of *E. coli* strain P10a (071:K? : H12) were obtained from I. and F. Ørskov of the International Escherichia Center, Copenhagen. Culture conditions are described elsewhere<sup>4</sup>. The lipopolysaccharide was isolated by extraction with 45 per cent phenol at 65°C for 10 min and purified by repeated centrifugation at 105,000g (ref. 5). The sugar components of the lipopolysaccharide are heptose, 2-keto-3-deoxyoctonate (KDO), galactose, glucose, rhamnose, glucosamine, galactosamine, and the new amino sugar (amino sugar X). It should be mentioned that glucosamine is present in lipid A only and is no constituent of the polysaccharide. From the hydrolysate (2 normal hydrochloric acid, 100°C, 3 h) of the lipopolysaccharide neutral sugars were removed on small (1.5 × 20 cm) columns of 'Dowex 50-H+' by percolation with water. Amino sugars were then eluted with 0.5 normal hydrochloric acid. The amino sugar fraction (glucosamine, galactosamine, and amino sugar X) was resolved by fractional elution with 0.33 normal hydrochloric acid from long (1.2 × 80 cm) columns of 'Dowex 50-H+' × 10 at a flow rate of 2 ml/h. After evaporation of the hydrochloric acid, the amino sugar remained as an oil which could not be crystallized.

Amino sugar X was N-acetylated with acetic anhydride/sodium bicarbonate according to Roseman and Ludowieg<sup>6</sup>.

When sprayed with periodate followed by nitroprussid/piperazine both amino sugar X and its N-acetyl derivative formed blue spots on paper chromatograms. This reaction is specific for deoxysugars<sup>7</sup>. During periodate oxidation (pH 4.5) of amino sugar X as well as of the N-acetylated amino sugar acetaldehyde was liberated, which was determined by the colour reaction with *p*-hydroxydiphenyl<sup>8,9</sup>. In the conditions used—microdistillation of acetaldehyde into the reagent—the determination

was not impaired by formaldehyde. This was verified by analysing the absorption spectrum of the colour reaction. Maximum absorption was at 570 m $\mu$  (for acetaldehyde  $\lambda_{\max}$  = 570 m $\mu$ ; for formaldehyde  $\lambda_{\max}$  = 646 m $\mu$ ). Formation of acetaldehyde during periodate oxidation is indicative of a 6-deoxy-group in amino sugar X.

Amino sugar X did not react in the Morgan-Elson assay modified according to Strominger *et al.*<sup>10</sup>. After controlled periodate oxidation, however, the *N*-acetylated amino sugar X was reactive in the Morgan-Elson assay. This modification was introduced by Ashwell *et al.*<sup>11</sup> as a specific test for 3-amino sugars.

From the results described so far we conclude that amino sugar X is a 3-amino-3,6-dideoxyhexose.

For further identification of amino sugar X its elution pattern from 'Dowex 50-H<sup>+</sup>' was compared<sup>12</sup> with those of 3-amino-3,6-dideoxy-D-galactose, 3-amino-3,6-dideoxy-L-glucose, 3-amino-3,6-dideoxy-D-mannose and 3-amino-3,6-dideoxy-L-talose. Peak positions relative to glucosamine are given in Table 1.

Table 1. RESULTS OF CHROMATOGRAPHY ON 'DOWEX 50-H<sup>+</sup>'  $\times 10$  OF AMINO SUGAR X AND REFERENCE SUBSTANCES

Amino sugar	Peak position, relative to glucosamine
Amino sugar X	1.37
3-amino-3,6-dideoxy-D-galactose	1.54
3-amino-3,6-dideoxy-L-glucose	1.38
3-amino-3,6-dideoxy-D-mannose	1.28
3-amino-3,6-dideoxy-L-talose	2.35

Column dimensions: 0.8  $\times$  55 cm; eluted with 0.33 normal hydrochloric acid at a flow rate of 2 ml./hr; 1 ml. fraction; tested with ninhydrin.

Table 2. PAPER CHROMATOGRAPHIC MOBILITIES OF *N*-ACETYLATED AMINO SUGAR X AND REFERENCE SUBSTANCES

<i>N</i> -acetyl-amino sugar	Mobility, relative to fucose, in		
	A	B	C
<i>N</i> -acetyl-amino sugar X	1.32	1.52	1.38
3-acetamido-3,6-dideoxy-D-galactose	1.23	1.42	1.18
3-acetamido-3,6-dideoxy-L-glucose	1.32	1.52	1.38
3-acetamido-3,6-dideoxy-D-mannose	1.38	1.60	1.60
3-acetamido-3,6-dideoxy-L-talose	1.50	1.92	2.33

Whatman No. 1 paper; descending chromatography in solvents, A: pyridine/*n*-butanol/water (4 : 6 : 3); B: *n*-butanol/acetic acid/water (5 : 1 : 2); C: pyridine/ethyl acetate/water (10 : 36 : 11.5); stained with alkaline silver nitrate<sup>13</sup>.

As can be seen from Table 1, amino sugar X has the same elution value as 3-amino-3,6-dideoxy-L-glucose. Paper chromatography of the *N*-acetylated amino sugar in three different solvents (Table 2) also indicates identity of amino sugar X and 3-amino-3,6-dideoxyglucose.

On paper chromatograms in solvent systems A, B, and C, free amino sugar X and 3-amino-3,6-dideoxy-L-glucose had identical mobilities and could be differentiated from the other reference substances. *R<sub>F</sub>* values vary on individual chromatograms, however, and are not easily reproducible.

Quantitation of amino sugar X was hampered by its instability, a property which it shares with 3-amino-3,6-dideoxy-L-glucose<sup>14</sup>. Following hydrolysis for 3 h (4 normal hydrochloric acid) 7 per cent of amino sugar X was found in the lipopolysaccharide using the procedure of Ashwell<sup>11</sup> with 3-acetamido-3,6-dideoxy-D-galactose as reference. On prolonged hydrolysis this analytical value decreases (4 per cent of amino sugar X after 12 h).

To the best of our knowledge 3-amino-3,6-dideoxyglucose has not previously been found in bacteria. The *N*-dimethyl derivative of the D-enantiomer was shown to be a constituent of carbomyein<sup>1</sup>, which was proved by synthesis<sup>14</sup>. Meanwhile we have detected amino sugar X in several other strains of *E. coli*.

We thank Drs I. and F. Ørskov for the *E. coli* strain and the culture of the bacteria, Dr G. Ashwell for a gift of 3-acetamido-3,6-dideoxy-D-galactose, Dr J. D. Dutcher for a sample of 3-amino-3,6-dideoxy-D-mannose, and Dr R. C. Richardson for methyl-3-amino-3,6-dideoxy-L-glucoside and methyl-3-acetamido-3,6-dideoxy-L-taloside. We also thank Miss Ch. Heidkämper for technical assistance.

Note added in proof (June 26, 1967). Meanwhile, 3-amino-3,6-dideoxyglucose has also been found in lipopolysaccharides of *Citrobacter* and *Salmonella* (Lüderitz, O., *et al.*, *J. Bact.*, **93**, 1681; 1967).

## MICROBIOLOGY

### Density Dependent Inhibition of Cell Growth in Culture

Abercrombie and Heaysman<sup>1</sup> coined the term 'contact inhibition' to describe the arrest of locomotion of animal cells which are in contact with one another. It was based on various parameters such as the behaviour of fibroblasts migrating from confronting explants, speed of movement in relation to numbers of contacts between cells, and nuclear overlap counts. Phase contrast cinematography of living cells by Abercrombie and Ambrose<sup>2</sup> later confirmed that the inhibition of movement depended on contact between cells. During these experiments it was found that certain sarcoma cells were less sensitive to inhibition than normal fibroblasts, and that they moved freely over one another and over normal cells<sup>3</sup>.

The concept of contact inhibition has attracted particular interest since the advent of tissue culture investigations on neoplastic transformation. Cells transformed by tumour viruses, *in vitro* or *in vivo*, show a marked tendency to pile up in culture in disorderly array, and to form layers several cells thick, in contrast to their untransformed precursors which tend to form monolayers of cells arranged in parallel. This change from the normal pattern has been attributed to loss of contact inhibition of movement, which in at least one instance has been confirmed by time-lapse cinematography (Ambrose, E. J., and Sheppley, K., personal communication, 1964).

Normal cells also differ from transformed cells in other characteristics, however, and the use of the term contact inhibition has been gradually extended to explain other phenomena, such as restriction of growth in dense cultures. We wish to suggest that the extension in use of this term is misleading, because it carries the implication of a common mechanism for which no evidence exists at present.

The notion that immediate contact between cells inhibits growth as well as movement has arisen from the tendency of cells to form monolayers and for the cell sheets formed to grow slowly, if at all, despite the continuing abundance of nutrients in the medium. Abercrombie originally suggested that this tendency to form monolayers may result from arrest of movement in contiguous cells, but he has not claimed that the contiguity between

cells is also responsible for inhibition of growth<sup>4</sup>. Unfortunately, movement of cells is not usually investigated by those investigating their growth and no precise work has been reported to show that the two are correlated. The available evidence in fact suggests that inhibition of movement and of growth are unrelated.

Cells of the BHK21 line, for example, form well oriented cell sheets and have been shown by time-lapse cinematography to be subject to contact inhibition of movement; yet they will grow to form multilayers with the same densities as their transformed derivatives which have lost movement inhibition<sup>5,6</sup>. We have also found independently that freshly isolated fibroblasts will continue to grow, without decrease in rate, for some time after they have formed monolayers in culture, provided that the medium is frequently changed<sup>7</sup>, or that the volume is large in relation to cell covered surfaces<sup>8</sup>. With continuous perfusion of fresh medium, Kruse and Miedema<sup>9</sup> produced multilayers of normal cells 5-17 cells thick, with no diminution of growth rate at the monolayer stage. Despite the absence of direct investigation of movement, these observations are scarcely compatible with the notion that growth and movement are simultaneously inhibited through a common mechanism which depends on surface contact between cells.

This is not to deny that in conventional culture conditions there are restrictions on cell growth which are apparently related to the population density of the cells<sup>10,11</sup> and which may be particularly important in connexion with the change following neoplastic transformation. Even with rapid exchange of medium, the growth of multilayered dense cultures of normal cells eventually slows or stops. Certain cell types such as 3T3 cells are particularly sensitive to this density restriction, in contrast to their transformed derivatives<sup>12</sup>.

It is even possible that contact might still play a part in inhibiting growth, but on a different basis from that involved in movement inhibition. For example, a small diffusible inhibitor might achieve an effective intracellular concentration in dense cultures with highly contiguous cell membranes through direct transfer from cell to cell and not through the medium where dilution or inactivation could occur<sup>13-15</sup>.

There is at present no direct evidence that contact is the primary requirement for the inhibition of growth, however, and other attributes of dense cultures should therefore be considered. One explanation which has not been subjected to rigorous analysis is that dense cultures may alter the extracellular environment in their immediate vicinity without making significant changes which can be detected in the bulk medium. Cells add and remove a variety of molecules in their immediate environment and there must be a series of concentration gradients which extend outwards from the cell membranes.

On first consideration this may seem unlikely to cause strong local effects close to the cell surface because in most cultures there is continuous agitation by vibration and thermal convection and a deliberate increase in mechanical agitation does not noticeably affect cell growth. Experimental observations and theoretical consideration of flow theory, however, show that fluid in the immediate vicinity of a solid-liquid interphase moves at a rate approaching zero, whatever the turbulence in the bulk fluid. As a result, movement in medium close to the cell surface will be restricted to molecular diffusion<sup>16</sup>. Concentration gradients will be maintained and not be greatly disturbed by movement in the overlying medium.

Thus it is quite possible that inhibitory conditions obtain in the immediate vicinity of cells in dense cultures and yet the bulk of the medium may retain the capacity for support of cell growth in another culture. For example, the local inhibitory conditions could result from accumulation of inhibitory molecules, depletion of nutrients, or local changes in pH or oxygen tension. In fact, it can be shown that a large number of cells attached to one surface

can inhibit the growth of a small number of cells on another surface if the distance between the two surfaces is small<sup>16</sup>.

It is not the purpose of this communication to examine these various hypotheses in depth, and the exercise would be of little value without further experimental data. We simply wish to draw attention to the inappropriateness of the term contact inhibition for use in relation to growth. It is misleading in that it implies a common mechanism for inhibition of cell growth and movement and it may misdirect the attention of investigators by tacitly implying a direct and immediate contiguity between cell surfaces as the basis for growth inhibition.

We therefore propose that the term "density dependent inhibition" be used to describe the restriction of growth in crowded cultures of animal cells, and that contact inhibition be restricted to arrest of movement as defined by Abercrombie and Heaysman<sup>1</sup>.

## Haemagglutinin of Rubella Virus

STEWART and his associates have developed a method for detecting a haemagglutinating antigen for rubella virus<sup>1</sup> which depends on two discoveries: first, that the calf sera ordinarily incorporated into media for the maintenance of cells infected with rubella virus contain an inhibitor for haemagglutination and, second, that the best agglutination was seen with blood cells from newly hatched chicks. In their original method BHK21 cells, which have been shown to produce the virus in high titre<sup>2</sup>, were infected with rubella virus and maintained in 2 per cent kaolin-treated foetal calf serum. Although this method provided a signal advance in the serology of rubella, in our laboratory production of haemagglutinin has been variable and, when found, the peak titres observed were only 1/32 per ml.

During an investigation of the nature of the rubella haemagglutinin, we have found a simpler method for its preparation. When tissue culture media containing normal foetal calf serum from infected cell cultures were placed on a 5 per cent to 60 per cent preformed sucrose density gradient, the haemagglutinin and infectivity appeared in the fractions around the density 1.18 g/ml. while the serum inhibitor remained at the top of the gradient (Table 1). Haemagglutinin could be demonstrated only when EDTA was incorporated in the gradient. It was then found that addition of 0.01 molar EDTA (final concentration) to crude tissue culture fluid and incubation for 2 h at 4° C, followed by centrifugation at 32,000 × g (16,000 r.p.m.) in a Servall RC2 for 2 h, resulted in sedimentation of haemag-

glutinin. After suspending this sediment in one-fifth the volume of phosphate buffered saline, we have obtained haemagglutinin titres of 1/256 and 10<sup>7.9</sup> P.F.U./ml. of virus. A titre of 1/640 was obtained when a sediment was re-suspended in one-tenth the original volume. Thus with this technique it is possible to prepare concentrates of haemagglutinin from large volumes of ordinary tissue culture fluid.

The mechanism for the effect of EDTA appears to be the removal of cations which may attach the inhibitor to the virus, because addition of calcium or magnesium chloride to the tissue culture fluids prevented the release of haemagglutinin from EDTA-treated fluids.

The fact that rubella haemagglutinin and infectious virus were associated with each other in the density gradients agrees with our observation that haemagglutinin produced by cells maintained with kaolin-treated serum<sup>1</sup> can be sedimented and does not pass a 100 m $\mu$  filter except after treatment with 'Tween'-ether (Table 2). Rubella haemagglutinin prepared from tissue culture fluid is therefore not a soluble antigen.

This investigation was supported by US Public Health Service research grants from the National Institute of General Medical Sciences and the National Institute of Allergy and Infectious Diseases.

### Application of Particle-counting to a Leafhopper-borne Virus

THE electron microscope particle-counting technique of Backus and Williams<sup>1,2</sup>, which involves the use of shadow-cast specimens, has been generally favoured in investigations of viruses involving particle counting. Watson<sup>3</sup> modified the method by using phosphotungstate negative

staining<sup>4,5</sup> to reveal the virus particles in more structural detail and to make identification easier. The modification facilitates counting of virus particles in relatively impure preparations.

We have used the electron microscope particle-counting technique of Backus and Williams<sup>1</sup>, as amended by Watson<sup>3</sup>, to estimate concentrations of wound-tumour virus (WTV) in extracts from root tumours of sweet clover plants and from the insect vector infected with the virus. The method also permitted the determination of several other parameters for WTV.

Root tumours from infected sweet clover plants, *Melilotus officinalis* (L.) Lam, Clone C<sub>10</sub> (refs. 6 and 7), were generally used as a source of WTV. The clarified tumour extract used for electron microscopy was prepared by triturating the tumours with pestle and mortar in three times their weight of a solvent, containing 0.05 molar potassium phosphate and 0.01 molar sodium sulphite, until the pulp attained the consistency of a finely ground meal. The crude extract at approximately pH 7.0 was squeezed through one layer of cheese cloth and then clarified in a Servall SS-1 centrifuge for 5 min at 7,200 r.p.m. In order to estimate the concentration of wound-tumour virus in infected leafhoppers, *Agallia constricta* Van Duzee, healthy nymphs in about the second instar were exposed to crimson clover (*Trifolium incarnatum* L.) infected with WTV until the infective virus attained a maximum concentration<sup>8</sup>. Then samples of forty to sixty infected leafhoppers were collected at random, counted and triturated in 0.1–0.2 ml. of a solution containing 0.1 molar glycine and 0.01 molar magnesium chloride adjusted to pH 7.0 with 1 normal sodium hydroxide. The crude extract was transferred to a cellulose nitrate tube (size 3/16 × 5/8 in.) by means of a Pasteur pipette. The preparation was centrifuged as described here by supporting the tubes in special 'Lucite' adapters made to fit the tubes of a Servall SS-1 centrifuge. The supernatant containing the virus was carefully removed with a 22 gauge needle fitted to a 1 ml. syringe, avoiding the fat layer floating on the surface of the extracts. These extracts were used for electron microscopy. The percentage of infected insects in the colony was assessed by haemagglutination tests<sup>9</sup> on twenty-five individual insects taken at random from the population, and on this basis the concentration was corrected to represent the number of extractable particles from infected insects only. The weight of an insect was always taken to be 1 mg.

The polystyrene latex suspension used consisted of particles 0.126 ± 0.0043 $\mu$  in diameter and was supplied by the Dow Chemical Company from Run No. LS-052-A. The concentration of particles was calculated from the dry weight of a given volume<sup>2</sup>. For electron microscopy, 0.1 ml. of the clarified tumour or insect extract prepared at or near 0° C, as described here, was mixed with 0.1 ml. of the latex suspension (diluted to contain 9.34 × 10<sup>11</sup> particles/ml.). To this suspension 0.2 ml. of 2 per cent potassium phosphotungstate and 0.05 ml. of a 1.0 per cent solution of bovine serum albumin were added. The mixture was sprayed from a commercial low pressure atomizer onto electron microscope specimen grids coated with a parlodion film stabilized with a second film of evaporated carbon. The grids were scanned in a Hitachi model HU-11A electron microscope at a constant magnification of × 7,000. Two grids were usually examined for each sample, and nine or ten droplets were photographed in each sample. Virus and latex counts were made on the original negative. The consistency of the ratio of virus particles to latex particles in a number of droplets was checked statistically by means of the  $\chi^2$  test, and the error in each count was estimated from the 95 per cent confidence limit calculated as previously described<sup>2</sup>.

The virus concentration of WTV isolate VI<sub>64</sub>, expressed as number of particles extracted/g of tumours, was 14.31 ± 1.76 × 10<sup>11</sup> in one experiment and 11.07 ± 1.20 × 10<sup>11</sup> in another.

Assuming the weight of a single leafhopper to be 1 mg, the average number of extractable virus particles/g of infected leafhoppers was  $9.6 \pm 1.0 \times 10^{11}$  in one experiment and  $14.0 \pm 3.5 \times 10^{11}$  in another. The maximum concentration of virus in the leafhopper is therefore almost exactly the same as that in the sweet clover tumour.

It was possible to determine, by direct particle count, the concentration of virus for the peak region of the curve of virus increase and decline in the insect vector after acquisition of virus by feeding on infected plants. Reddy and Black<sup>8</sup> had earlier determined this same curve for a greater range of concentration by measurements of relative infectivity. An average curve for relative infectivity constructed from their Fig. 7 corresponded closely with our count of virus particles in the region of the peak. We concluded that the two peaks could be equated and that, at the peaks, their relative infective virus concentration of  $10^{7.72}$  equals our concentration of  $10^{9.26}$  virus particles per infected leafhopper. Any virus concentration value on their relative scale can be converted to the number of virus particles per ml. of solution injected into assay leafhoppers by multiplying their value by  $10^{2.54}$ . Information from the curves permits the determination of the minimum infective dose for injection of a leafhopper as  $10^{2.6}$  virus particles. This value compares with a minimum infective dose of between  $10^{4.4}$  and  $10^{4.6}$  for the inoculation of cultures of the vector cells (Gámez, R., and Chiu, Ren-jong, personal communication).

In duplicate experiments comparisons of the concentration of extractable virus/g of tumour incited by WTV isolates VI<sub>66</sub> and VL<sub>49</sub> yielded values of  $14.2 \times 10^{11}$  and  $11.2 \times 10^{11}$  for the former and  $1.6 \times 10^{11}$  and  $0.4 \times 10^{11}$  for the latter. Other isolates had intermediate concentrations roughly related to the length of time they had been maintained in sweet clover without passage through the vector.

It was also established that the current purification procedure isolates only 2.5 per cent of the virus extracted from the tumours, and that 1 mg of protein in this purified virus corresponded in duplicate experiments to  $7.1 \times 10^{12}$  and  $7.7 \times 10^{12}$  virus particles.

At serological end-points determined by the precipitin ring test and indirect haemagglutination the number of virus particles/ml. in duplicate experiments was  $4.0$  and  $9.2 \times 10^9$  and  $8.1$  and  $40.0 \times 10^7$ , respectively (unpublished results of Gámez and MacLeod).

On the basis of serological data and Merrill's curve<sup>10</sup>, Black<sup>7,11</sup> had estimated values for the concentration of WTV in tumours, leafhoppers, and the minimal infective dose for the vector, which were close to the same order of magnitude as the more direct and precisely measured values presented here.

This research was supported in part by grants from the National Science Foundation, the US National Institutes of Health and a scholarship to R. G. from the Rockefeller Foundation.

### Interferon and Murine Leukaemia. III: Efficacy of Interferon Preparations administered after Inoculation of Friend Virus

INTERFERON has been most effective *in vitro* and *in vivo* when administered before viral inoculation, considerably less effective when inoculated at the same time as the challenge virus, and often ineffective after viral inoculation<sup>1-3</sup>. The necessity of pretreatment of cells or animals to obtain an anti-viral effect has raised doubts as to the value of interferon in the treatment of viral diseases<sup>4-5</sup>.

We have shown that concentrated preparations of interferon inhibited the development of splenomegaly in Friend disease as long as mice were treated with interferon before viral challenge and twice daily thereafter<sup>6,7</sup>. Administration of interferon for only 3 days was ineffective although treatment preceded inoculation of virus. These results contrasted with those obtained in mice treated with interferon and inoculated with encephalomyocarditis and Semliki forest viruses. In these acute lethal diseases, interferon had a prophylactic effect and afforded only negligible protection after viral inoculation<sup>8,9</sup>.

This communication reports the results of experiments in which treatment with interferon initiated 48 h after inoculation of Friend virus inhibited the development of splenomegaly in Swiss mice. We think that these are the first results which show interferon preparations to possess significant anti-viral activity after infection has been well established in the animal host.

The methods of preparing and titrating Friend virus have been described before<sup>6,7</sup>. Swiss mice, 4-6 weeks old, were inoculated intraperitoneally with 0.2 ml. of a 15 per cent extract of leukaemic spleen. Spleen weight at the end of the experiment served as a criterion of disease<sup>10</sup>. Mouse interferon was prepared by the method of Finter<sup>11,12</sup>. The brains of diseased weanling mice infected with West Nile virus were ground in a mortar and the interferon was extracted as described before<sup>7</sup>. To increase the interferon titre, preparations were concentrated ten-fold by pressure dialysis. Control normal mouse brain was extracted by techniques identical to those employed in the preparation of interferon. The interferon preparations were assayed by standard techniques with mouse embryo fibroblasts in monolayer cultures challenged with 50-100 P.F.U. of vesicular stomatitis virus. Interferon titres were expressed as the dilution (2 ml.) of the original preparation responsible for a 50 per cent reduction in the number of plaques as compared with virus control cultures<sup>13</sup>.

Table 1 summarizes the results of two experiments designed to evaluate the effect of mouse brain interferon on the development of splenomegaly in Swiss mice infected with Friend virus. In one of the two treatment groups, interferon was administered intraperitoneally

Fig. 1. Spleen of uninoculated Swiss mouse stained with haematoxylin and eosin ( $\times c. 660$ ). Note absence of immature cells.

In experiment 1 Swiss mice, male and female, were killed 22 days after viral inoculation. In experiment 2 Swiss mice, female, were killed 16 days after viral inoculation. (1) The virus was a 15 per cent extract of leukaemic spleen and 0.2 ml. was injected intraperitoneally. (2) In this group interferon treatment initiated 24 h and 3 h before inoculation of Friend virus was continued twice daily until the end of the experiment. Treatment consisted of twice daily injections of 0.2 ml. of interferon intraperitoneally. (3) In this group interferon treatment initiated 48 h after inoculation of Friend virus was continued twice daily until the end of the experiment. Treatment consisted of twice daily injections of 0.2 ml. of interferon intraperitoneally. (4) Titre of interferon employed was 56,000/2 ml. (5) Titre of interferon employed was 44,000/2 ml. Spleen weight was the geometric mean spleen weight in mg. Mean  $\pm$  S.E. was the geometric mean in logarithms  $\pm$  standard error.

24 h and 3 h before inoculation of Friend virus and twice daily thereafter. In the other group, interferon treatment was initiated 48 h after viral inoculation and twice daily thereafter.

There was no significant difference between the mean spleen weights of the two viral control groups (that is, those mice receiving virus alone and those mice receiving virus and concentrated normal mouse brain). A significant inhibition of splenomegaly, however, was observed in both groups of mice treated with interferon compared with the two viral control groups. (Experiment 1:  $P < 0.0001$ ; experiment 2:  $P = 0.001$ ). There was no significant difference between the mean spleen weights of the two groups of mice treated with interferon.

At the termination of these experiments most of the untreated leukaemic mice had large spleens in which the normal parenchyma was extensively replaced by "Friend cells" (Fig. 2)<sup>14</sup>. Relatively small spleens with only scattered foci of Friend cells were noted in a few of the untreated mice. Of the interferon treated mice, a considerable number had small spleens, and these could not be distinguished histologically from the small spleens of the untreated leukaemic mice. In the larger spleens of mice treated with interferon, however, not only was the extent of Friend cell involvement less marked than that observed in control leukaemic mice, but there appeared to be numerous foci of erythroid maturation involving the primitive Friend cells (proerythroblast), and their

Fig. 2. Spleen of untreated leukaemic Swiss mouse stained with haematoxylin and eosin ( $\times c. 660$ ). Note sheet of large immature "Friend" cells.

Fig. 3. Spleen of leukaemic Swiss mouse treated with interferon, stained with haematoxylin and eosin ( $\times c. 660$ ). Note large immature "Friend" cells at right and focus of erythroid maturation on the left.

conversion to normoblastic elements (Fig. 3). This cellular maturation was seldom observed in the spleens of untreated leukaemic mice. A similar phenomenon has been observed before in Swiss mice infected with Friend virus and treated with erythropoietin (unpublished work, F. Zajdela); namely, inhibition of splenomegaly accompanied by histological evidence of erythroid maturation.

The therapeutic effect of administration of these interferon preparations after inoculation of Friend virus clearly demonstrated that in this system interferon pretreatment was not essential. Other viral diseases characterized by a long latent period or a sub-acute or chronic course may also be attenuated by adequate interferon treatment after viral infection.

### Failure of Bacteriophage $\phi$ X 174 to multiply in Serum Spheroplasts

SPHEROPLASTS are bacteria that are deficient in cell wall and can be prepared by a variety of methods from Gram-negative bacteria. One way to examine the degree of cell wall removal is to study the infection of spheroplasts with bacteriophage, which attaches to receptors on the cell wall. Bacteriophage adsorption and multiplication in spheroplasts have been reported by a number of authors<sup>1-7</sup>. The ability of spheroplasts prepared by treatment with serum to multiply phage has not yet been investigated.

We compared the capacity of spheroplasts, made with serum and by three other methods, to adsorb and multiply  $\phi$ X 174 bacteriophage. Spheroplasts were prepared from *Escherichia coli* C in the log phase of growth. Lysozyme spheroplasts were prepared by treatment with EDTA, tris, and lysozyme (ETL) as described<sup>8</sup>. Glycine spheroplasts<sup>9</sup> were made from bacteria suspended in brain-heart infusion broth containing 3 per cent glycine and 0.02 molar magnesium chloride. The suspension was aerated by bubbling air through the broth. The transformation of the bacteria to spheroplasts was virtually complete after 80 min. Penicillin spheroplasts were prepared by the method of Lederberg<sup>10</sup>, and serum spheroplasts were prepared as previously described<sup>11</sup>. Briefly, serum from a healthy adult donor was added to suspension of bacteria in brain-heart infusion broth with 0.01 molar magnesium chloride. After 30 min the transformation of rods to spheroplasts was complete.

Spheroplasts were collected by centrifugation, resuspended in brain-heart infusion broth with 0.05 molar magnesium chloride, and adjusted to an optical density (OD) of 0.15 at 650 m $\mu$ . The addition of magnesium and the use of broth both seemed to be essential to the prolonged stability of spheroplasts. About 10–20 per cent of the spheroplasts lysed during centrifugation and resuspension. The final suspensions therefore contained about 80–90 per cent spheroplasts and the remainder of the bacterial forms were ghosts. Less than 1 per cent of the bacterial forms in the final suspensions were rods.

Bacteriophage  $\phi$ X 174 was grown and purified as described by Adams<sup>12</sup>. Phage was added to the spheroplast suspensions in a ratio of 10 plaque-forming units

Fig. 3. Phage multiplication in serum spheroplasts. Symbols as in Fig. 2.

(P.F.U.) to bacterial form. Two control tubes were run with each experiment. One control consisted of bacteriophage alone; all phage suspensions remained stable during the hour of incubation. The second control tube contained suspensions of spheroplasts without bacteriophage. The spheroplast suspensions remained stable for more than 1 h without significant change in OD or in the differential count of spheroplasts and ghosts.

After bacteriophage was added, samples were taken at 10 min intervals for 1 h of incubation at 37°C. For differential counts, samples were fixed in 2 per cent formalin and were examined using a phase contrast microscope. The optical density was determined, and samples were taken for determination of phage titre by the agar-layer method. Samples for phage titre were diluted in saline with 0.05 molar magnesium chloride.

For comparison with phage multiplication in spheroplasts, *E. coli* C rods were infected with bacteriophage, and changes in bacterial morphology and phage titres were measured in a similar manner (Fig. 1). The phage titre decreased at 10 min and then rapidly increased. The OD increased slightly in the first 20 min, but then decreased to 40 per cent at 60 min. At 30 min the rods began to lyse by changing into rod-shaped ghosts. The change in rod morphology ran parallel with the change in optical density and the increase in phage titre. At 60 min only 2.5 per cent normal rod forms remained.

The results of experiments with ETL, glycine and penicillin spheroplasts were similar. As an example, phage multiplication in glycine spheroplasts is shown in Fig. 2. Phage adsorption proceeded as with the normal rods, but the phage titre began to increase earlier. Remarkably, neither the OD nor the differential count changed during the experiment. Spheroplasts did not lyse but became larger and somewhat paler, as did the uninfected spheroplasts in control tubes.

In sharp contrast, little phage adsorption and multiplication occurred with the serum spheroplasts (Fig. 3). Furthermore, there was no evidence of phage multiplication when the spheroplasts were lysed by freezing and thawing.

Fig. 1. Phage multiplication in *E. coli* C. ●—●, Phage; ▲—▲, optical density; +—+, rods; □—□, spheroplasts.

Fig. 2. Phage multiplication in glycine spheroplasts. ●—●, Phage; ▲—▲, optical density; □—□, spheroplasts.

The effect of human serum on glycine spheroplasts was also studied. Glycine spheroplasts were treated with human serum for 20 min, resuspended in broth and infected with phage. Glycine spheroplasts treated with human serum did not support phage multiplication. Treatment of glycine spheroplasts with serum inactivated by heat had no effect on phage multiplication.

When phage multiplication in normal rods is compared with that in penicillin, glycine, and ETL spheroplasts, there are two striking differences. The first is that the phage titre increases more rapidly in the spheroplast suspensions. The loss of part of the cell wall may allow more rapid penetration of phage into spheroplasts. This view is supported by reports that some phage DNA particles infect spheroplasts but not intact bacteria<sup>12</sup>. The second notable difference is that the rods lysed after infection and the spheroplasts did not. Infection of rods by  $\phi$ X 174 may activate an autolytic enzyme in the bacteria<sup>14</sup>. Either the autolytic enzyme is not induced or it is not effective in spheroplasts. The presence of magnesium as a stabilizing agent in the spheroplast suspensions does not seem to be the cause of the lack of lysis because normal rods lysed in the presence of magnesium. One strain of bacteria is known to produce phage without lysis of the host organism<sup>15</sup>. The mechanism of phage multiplication and release in that strain may be similar to that in the spheroplasts.

Spheroplasts have been the subject of considerable interest, because they retain many of the metabolic capacities of the parent organisms<sup>16</sup>. As shown here, spheroplasts prepared by different methods may have different properties. Serum treatment may have damaged the phage receptor sites while the other methods of spheroplast preparation did not.

We thank Drs Ralph J. Wedgwood and Yi-Chuan Ching for helpful discussions. This investigation was conducted under the sponsorship of the Commission on Immunization of the Armed Forces Epidemiology Board and was supported in part by a contract with the Office of the Surgeon General, Department of the Army, by grants from the US National Institutes of Health, and by State of Washington Initiative Funds.

### Comparative Growth of *Candida lipolytica* on Glucose and *n*-Hexadecane

MUCH attention has been paid to yeasts grown on hydrocarbons since Champagnat<sup>1</sup> suggested their potential use as fodder-yeast. Few differences have as yet been reported to be induced in these yeasts by the hydro-

Table 1. YIELD OF *Candida lipolytica* GROWN ON GLUCOSE AND ON *n*-HEXADECANE

Phase	Substrate	
	Glucose	<i>n</i> -Hexadecane
Exponential	2.00* ( $\sigma = 0.31$ )	1.99 ( $\sigma = 0.59$ )
Stationary	2.22 ( $\sigma = 0.13$ )	3.96 ( $\sigma = 0.51$ )

\* g/10<sup>11</sup> dry cells.

Cells were collected in the exponential phase when the broth contained 10<sup>8</sup> cells/ml. and in the stationary phase 1 day after the growth curve levelled off. Dry weights were obtained by drying equal portions of the washed cell crop at 105° C for 3 h. For comparison, the cell yield was calculated for 1 l. broth and at a cell concentration of 10<sup>8</sup> cells/ml. in all cases. Each value is the mean of at least ten separate experiments.

carbons, other than an increase in their lipid content<sup>2,3</sup>. We wish to report a striking difference in the growth of *Candida lipolytica* when *n*-hexadecane replaces glucose as the sole source of carbon and energy.

*C. lipolytica* was obtained from the C.B.S. (Delft) as a pure strain, not as a mixture of two<sup>4</sup>. The original slant was twice sub-cultured on malt agar. One slant served to inoculate a 250 ml. flask containing 50 ml. of a yeast nitrogen base medium (Difco), to which 1 per cent (weight/volume) glucose (A.R.) or *n*-hexadecane (B.D.H.) was added. Incubation lasted for 3 days at 27° C on a rotatory shaker (E. Bühler, Tübingen, type 150100) at 140 r.p.m. The pH (about 6.5) was adjusted twice a day with 5 normal ammonia. Enough of this starter culture to make 10<sup>7</sup> cells/ml. was transferred to a 1 l. flask containing 200 ml. of the same medium. Incubation was resumed in the same way. The growth curve was then determined by plotting the number of cells present against time (Fig. 1). The break point *a* in the curve was always observed when *C. lipolytica* was grown on *n*-hexadecane.

An explanation for this phenomenon was found when cell yields in the exponential phase of growth were compared with those in the stationary phase (Table 1). The cells were collected by centrifugation at 16,300g for 30 min, in a refrigerated Sorvall 'RC II-B' centrifuge. The excess *n*-hexadecane solidified as a pellet at the surface and the yeast cells collected at the bottom of the cups when the broth was at room temperature at the beginning of the centrifugation and allowed to cool to +4° C during the run. Most of the cells were in the true yeast form when they were collected and little if any pseudomycelium was present.

From the break in the growth curve and the fact that individual cell weights increased by a factor of two, it appears that the culture on hydrocarbon, on reaching a certain age, shows a lesser tendency for cell division which is compensated by an increase in individual cell size. Thus *C. lipolytica* may well show an exponential

Fig. 1. Growth of *Candida lipolytica* on glucose (x) and on *n*-hexadecane (●). The cells were counted using a Thomas haemocytometer. Cell clusters were broken up by adding three drops of a 10 per cent ethanolic solution of 'Tween 80' per ml., and mixing for 1 min on a 'Whirlmix' (Cenco).

overall mass increase on both glucose and *n*-hexadecane, but in quite a different way. Further work is being carried out to correlate this varying growth behaviour with biochemical differences.

This investigation was supported by the Fonds National de la Recherche Scientifique. One of us (J. P. A.) is grateful to the F.N.R.S. for a fellowship.

### Electron Microscopy of Monkey Kidney Cells infected with both SV40 and Measles Virus

THE ultrastructure of cells infected with SV40 alone has been described previously by several investigators<sup>1-4</sup>. The morphology of the internal component of measles virus in infected cells has also been described<sup>5-7</sup>. Single cells infected with these two viruses have not been reported, however. In a previous study, a mixed infection with both SV40 and measles virus was obtained in a lot of cell cultures prepared from the kidney of a sick green monkey<sup>8</sup>. Mixed infection with these two viruses was later experimentally induced in tissue culture, and doubly infected cells were noted on examination by light microscopy<sup>9</sup>. The present communication describes the electron microscopy of cells in cultures doubly infected with SV40 and measles virus, and observation of the fine structure of both viruses in the same nucleus.

Primary kidney cells prepared from both African green and rhesus monkeys were used. Freshly trypsinized cells were seeded into 3 oz. prescription bottles or Leighton tubes containing 11 × 22 mm coverslips. SV5 antiserum to a final concentration of 0.2 per cent was added to a medium

consisting of Hanks balanced salt solution, 0.5 per cent lactalbumin hydrolysate, and 2 per cent calf serum. When confluent monolayers were obtained, the cultures were inoculated with measles virus and SV40, either simultaneously or in alternating sequence with an interval of 1-5 days between the first and second virus inoculations. All viruses were used in a multiplicity of 1 or greater. Infected cells were fixed for electron microscopy 3-7 days after the final inoculation, depending on the condition of the cell as observed by light microscopy. The infected cells in the prescription bottles were removed from the glass, centrifuged, and fixed in cold 3 per cent phosphate-buffered glutaraldehyde. They were then post-fixed in 1 per cent phosphate-buffered osmium tetroxide, dehydrated in graded alcohol, and embedded in 'Maraglas'. The infected cells on coverslips were left *in situ*, fixed as described and finally embedded in 'Epon'. All sections were examined with a Siemens-Elmiskop I electron microscope.

As shown in Fig. 1, the nucleus of a rhesus monkey kidney cell infected with both SV40 and measles showed many slightly electron-dense SV40 particles and, in addition, aggregates of fibrils, 150 Å in width, either linearly arranged or sectioned across their width. Morphologically, these fibrils were similar in appearance to the fibrils in the nuclei of measles-infected dog kidney cells described by Tawara<sup>6</sup>, and to those observed by us in the nucleus of a green monkey kidney cell infected with measles virus alone (Fig. 2). It is possible that these fibrils were the early development of the internal component of measles virus. In the same photograph (Fig. 2), coiled strands of filaments were observed in the cytoplasm of the cells infected with measles, which are identical in appearance to the internal component, described in recent reports, found in the cytoplasm of cells infected with other myxoviruses<sup>10,11</sup>.

In a study of SV40 in green monkey cells, Granboulan *et al.*<sup>12</sup> noted the presence of a similar fibrous structure in the nucleus of the SV40 infected cells during the process of cellular alteration, but considered these fibrils to be of unknown significance. Because "normal" monkey kidney cell cultures have often been found to harbour a variety of viruses, it appears that the structures observed earlier may be due to an unrecognized latent infection with measles virus or some other agent.

Mixed infections with two DNA viruses have been demonstrated by O'Connor *et al.*<sup>13,14</sup>. Both SV40 and an adenovirus, and SV40 and herpes simplex virus, have been

Fig. 1. Electron micrograph of a portion of a nucleus in a rhesus monkey cell showing low electron-dense SV40 particles (S) near the periphery of the nuclear membrane (M) and the linearly arranged fibrils (→) in the centre portion of the nucleus. (× c. 50,665.)

observed in the same nucleus. Other investigators have noted the occurrence of adeno-SV40 hybrids in monkey cells infected with these two viruses<sup>15,16</sup>. Evidence is presented here that one nucleus can be infected with both a DNA virus (SV40) and an RNA virus (measles). The phenotypic mixing of SV40 and measles would appear to be a possibility and is being studied.

Fig. 2. Electron micrograph of a portion of an African green monkey kidney cell infected by measles virus showing closely packed, linearly arranged fibrils (→) in the nucleus (N), and coiled strands of filaments (↪) in the cytoplasmic matrix (C). ( $\times 35,000$ .)

### Segregation during Transfer of Infectious Drug Resistance in Enterobacteriaceae

MANY reports of infectious drug resistance suggest that all the resistance determinants of a multiple resistant donor strain are invariably transferred to the sensitive recipient strain.

A new technique which we have developed has shown that, by using different recipients and different methods of selection, various patterns of resistance are obtained in colonies selected at random from the converted recipient population.

Equal volumes of overnight broth cultures of both donor and recipient strain were mixed in nutrient broth to produce a final dilution of 10 for each culture. After overnight incubation at 37° C, the mixed culture was plated on to a selective medium. This selective medium was tryptone soya agar (Oxoid CM 131) containing 15 µg nalidixic acid/ml. and one other antibiotic. Nalidixic acid was added because all the recipient strains used were mutants resistant to nalidixic acid<sup>1</sup>; this facilitates the isolation of the converted recipients from the donor strains which were all sensitive to nalidixic acid. The other antibiotic which was added to the selective medium depended on the resistance pattern of the donor strain. For example, if the donor strain was resistant to tetracycline, streptomycin and sulphonamide, three plates were used each containing one of these antibiotics in addition to nalidixic acid. The colonies which grew on these plates after incubation were formed by bacteria to which drug resistance had been transferred from the resistant donor strain. The converted recipients were purified on nutrient agar to free them from contamination by the donor strain.

A hundred colonies were selected at random, and individual bacterial suspensions were prepared from each purified colony. The pattern of resistance of the individual colonies was determined by growing the bacteria in drops of antibiotic solutions on the surface of flat 'Perspex' plates. These plates are modifications of those originally described for a complement-fixation test<sup>2</sup>. In the original method, the 'Perspex' plates were 16 in. square and 1/8 in. thick. These proved to be rather clumsy, and so smaller plates of the same thickness but only 12 in. square were substituted. The top surface of the plate was engraved with a centrally placed grid of a hundred 1 in. squares arranged in ten rows of ten. A rack to hold ten of these plates was constructed<sup>3</sup>.

To investigate the converted recipients, we sterilized the plates by immersion in 10 per cent hydrochloric acid, rinsed them in sterile distilled water, allowed them to dry and finally wiped them with petroleum ether.

Eight antibiotic solutions were prepared in tryptone soya broth. They were 25 µg/ml. of oxytetracycline; 12.5 µg/ml. of nalidixic acid; 12.5 µg/ml. of streptomycin; 100 µg/ml. of sulphonamide; 20 µg/ml. of furazolidone; 25 µg/ml. of neomycin; 30 µg/ml. of ampicillin; and 25 µg/ml. of chloramphenicol.

Each square in the tenth column of a 'Perspex' plate received two drops of tryptone soya broth, and each square in the ninth column received one drop of the broth from a dropping pipette calibrated to deliver 0.04 ml. With individually calibrated pipettes, 0.04 ml. of each of the eight selected antibiotic solutions was delivered on to the squares of the first eight columns of the plate so that each column contained a different antibiotic; the squares in the ninth and tenth columns received no antibiotic.

To each square in the first nine columns of the first row was added a drop of 0.02 ml. of a bacterial suspension. The square in the ninth column containing no antibiotic checked the viability of the culture and the square in the tenth column receiving no bacteria was a control of sterility. The next row on the plate received a drop of another bacterial suspension, and in this way ten individual bacterial suspensions could be accommodated on each plate and one hundred on the complete set of ten plates.

As an indicator, a sterile 0.1 per cent solution in distilled water of 2,3,5-triphenyltetrazolium chloride was prepared. With a calibrated dropping pipette, 0.02 ml. of this indicator solution was added to every square on the plates. As they were completed, the plates were placed in the rack, which was then put into a box and sealed to prevent evaporation of the drops. The box was incubated overnight at 37° C.

On the next day, the drug resistance pattern of the converted recipients was determined by inspection of the plates. If, in a particular pool on a 'Perspex' plate, the bacteria had multiplied they would have absorbed the tetrazolium salt and reduced it to a red formazan. That pool would therefore contain a red deposit and would be scored positive.

All the squares in the ninth column should be scored positive, because these squares contained no antibiotic, and the squares in the tenth column testing sterility should be negative. The pattern of red deposits in the first eight columns determined the resistance pattern of the individual suspensions.

With this technique we have shown that a converted recipient does not always receive the complete resistance pattern of the donor, but that the particular resistance markers which appear in the converted recipient depend on which antibiotic has been added to the selective medium and also on the type of sensitive recipient used. An example is shown in Table 1: three different resistance patterns can be recognized with the six antibiotics used.

The advantage of this new technique in comparison with the use of solid media or replica plating is that very

## RADIOBIOLOGY

### Radiation Dose due to the Cosmic Rays

THE present interest in the effects to populations of low levels of radiation exposure emphasizes the importance of accurate estimates of the dose due to the cosmic radiation. This dose has usually been estimated from measurements of the ionization produced in high pressure ionization chambers and the estimates have varied over a wide range of values. Lowder and Beck<sup>1</sup> have recently made a critical assessment of these measurements.

By far the principal components of the cosmic ray dose at sea-level are due to  $\mu$  mesons and cascade showers of electron-photons. The  $\mu$  meson dose is the larger of these two contributors. To calculate the  $\mu$  meson dose the energy lost by the  $\mu$  meson in the absorbing material is required together with the integrated intensity of the particles. Barnaby<sup>2</sup> and Crispin and Hayman<sup>3</sup> have discussed, with experimental verification, the energy loss theory for  $\mu$  mesons in an organic material. They showed that above about 300 MeV the average loss of energy by collision processes in a plastic phosphor (NE 102) is virtually constant at about 1.7 MeV/g cm<sup>2</sup>. The cosmic ray integrated intensity for  $\mu$  mesons at sea-level (lat. 50° N.) is 1.01 particles/cm<sup>2</sup>/min (ref. 4), of which at least 95 per cent have energies above 300 MeV, and the dose due to  $\mu$  mesons in plastic therefore becomes 15 mrad/year. The error in this figure would be less than  $\pm 1$  mrad/year. The average energy loss for a  $\mu$  meson of a given energy in an absorber is a function of both the ratio  $Z/A$  and density. The composition of the human body<sup>5</sup> is such that the mean  $Z/A$  is 0.550 compared with 0.545 for the plastic. The density of the plastic is 1.03 g/cm<sup>3</sup>, and therefore the tissue dose due to  $\mu$  mesons will not be significantly different from the dose in plastic at sea-level.

The contribution of the electron-photon showers is harder to estimate. If, however, we assume that the rate of energy loss is the same, then, using Rossi's figure for the

flux of the shower component, the total sea-level dose becomes  $21 \pm 2$  mrads/year. This figure is in reasonable agreement with the value of  $26 \pm 1.5$  mrads/year in water obtained by Lillierap<sup>6</sup> using Čerenkov radiation detection techniques.

The cosmic ray  $\mu$  meson flux in the basement of a five-storey London building has been measured using the large liquid scintillation counter described elsewhere<sup>7</sup>. The flux was found to be 0.63 particles/cm<sup>2</sup>/min. Because of the size of the counter (138 cm  $\times$  74 cm in area and 10 cm thickness) the measured figure is a value between the flux of particles traversing the counter in a downwards direction and the total flux extended over all directions. It is the latter that is needed for calculating the  $\mu$  meson dose. The ratio of these fluxes is 3:4. An accurate calculation of the total flux is difficult, but from the measured flux it cannot be greater than 0.84 particles/cm<sup>2</sup>/min. The contribution of the electron-photon shower in these conditions is very small and therefore the total tissue dose due to cosmic radiation is about 12 mrads/year.

The figures at present accepted for the cosmic-ray dose<sup>8</sup> are higher than the values given here. The probable reason for this lies in the different measuring techniques used and it is clear that further measurements using solid detectors are desirable, particularly because of the considerable variations among the various ionization chamber data.

### Depression of Reticulocytes by $\gamma$ -Globulin after Splenic X-irradiation

It has been suggested that local splenic X-irradiation leads to the release of a substance which inhibits mitosis<sup>1-3</sup>. It has also been found that when blood serum withdrawn from rabbits 3 h after local splenic X-irradiation is injected intramuscularly into normal healthy rabbits, it induces a similar drop in the number of reticulocytes as does an injection of blood plasma withdrawn from isolated spleens which had been irradiated<sup>3</sup>.

To isolate the substance responsible for this drop we fractionated the serum proteins of rabbits 3 h after their spleens had been irradiated with 400 r. (THX-250 X-ray apparatus, 180 kV, 15 m.amp, 0.5 mm copper, 30 cm focus skin distance, 111 r./min).

The serum was fractionated step by step by chromatography on DEAE-cellulose columns<sup>4</sup>. Five peaks were determined in diluted samples (see Fig. 1). The fractions were dialysed, concentrated by pervaporation, their homogeneity checked by paper electrophoresis and, when necessary, rechromatographed. By means of paper, starch-gel and free boundary electrophoresis, fraction I was shown to be homogeneous gamma-globulin.

Three mg of fraction I/kg body weight was injected intramuscularly into rabbits. A similar effect was observed

3-17 h after injection as on the first or second day after serum which contained 100 mg protein/kg was injected (ref. 4, see Table 1). Serum fraction I withdrawn from untreated rabbits had no such effect (see Table 2). Thus it would seem that the factor in the serum responsible for reducing the reticulocyte number after local splenic X-irradiation is associated with gamma-globulin obtained by DEAE-cellulose chromatography of the serum.

Table 1

It is possible that the same serum factor is responsible for inhibiting the growth of Jensen sarcoma<sup>5</sup> or fibroblast cultures<sup>7</sup>. It could well be the same factor, as is suggested by refs. 1 and 2, that is found to be released from the spleen following X-irradiation<sup>3,4</sup>.

Investigations are in progress to prove these results by experiments *in vitro*.

## Reduction of the Absorption and Retention of Strontium in Rats

THE absorption and retention of dietary strontium can be reduced by supplementing the diet with an equimolar mixture of barium and sodium sulphates<sup>1,2</sup>, calcium phosphates<sup>3</sup>, or sodium alginate<sup>4,5</sup>. The possibility of remedial measures to protect a population exposed to a high concentration of strontium-90 in the diet makes these results particularly interesting. Promising results have been obtained from each of the dietary supplementations, and the purpose of the present investigation was to compare the effectiveness of the different treatments in rats of the same strain and age in similar conditions.

Sixty-three female albino rats, 8-9 weeks old and weighing about 130 g, were used. All rats had been fed the standard diet (1.0 g calcium, 0.5 g phosphorus/100 g diet) with water *ad lib*. since weaning. They were divided into seven groups of nine animals each and fed for 8 days on the standard diet or diets supplemented with the additives shown in Table 1. On the sixth day, the rats were placed in separate metabolism cages and given tracer amounts of almost carrier-free strontium-85 and calcium-47 in the drinking water for 2 days before they were killed on the eighth day. Urine was collected from each rat during the last 3 days of the experiment and the gut was removed after death, before drying and ashing the separate carcasses. All assays of radioactivity were made on a single channel gamma scintillation counter<sup>6</sup>.

The results are shown in Table 1. The amounts of strontium-85 in the carcass and in the urine plus carcass are measures of the body retention and the absorption of the radioactive marker, respectively. For calcium-47, however, when dietary calcium is increased by supplementation with calcium and phosphorus, the body retention and absorption of the marker decreases, and the fall in the percentage of calcium-47 in the carcass and in the urine plus carcass which we observed is to be expected.

Table 2 shows the comparative absorption and retention of strontium relative to that in the control animals (no supplementation). It should be noted that the

Table 2. ABSORPTION AND RETENTION OF STRONTIUM-85

sulphate and phosphate supplementations were equimolar (60 mmoles/l.).

The decreased retention and absorption of strontium-85 shown in Table 2 were achieved with only about 30 per cent change in the absorption and retention of calcium. The combined therapy with alginate and calcium phosphate supplementation gave the greatest reduction in the strontium absorbed or retained that we have obtained so far from any dietary supplementation.

## PATHOLOGY

### Adverse Effects on Offspring of Tranquillizing Drugs during Pregnancy

It has recently been shown that the injection of certain tranquillizing drugs during pregnancy produces loss of weight and defects of maze learning depending on the stage of pregnancy in which the injections are given<sup>1</sup>. The same workers obtained inconclusive evidence of the effect of tranquillizers on conditioned avoidance training. The present study investigates further the possible effect on conditioning of such treatment and attempts to verify the effects on weight.

Twelve groups of female rats were used in a 4 × 3 factorial design. One independent variable, the drug administered, involved four groups—experimental subjects the mothers of which were given reserpine (Res), meprobamate (Mep), chlorpromazine (Chl), or distilled

water (control) during pregnancy. The three tranquillizing drugs are representative of three different chemical groups, respectively *Rauwolfia* derivatives, substituted propane-diols, and phenothiazine derivatives. The second major independent variable was whether the drug was administered in early, mid- or late pregnancy. The mothers were obtained from the Charles River Breeding Co., Boston, and were of a special Sprague-Dawley stock delivered by Caesarian section. The offspring were delivered normally and a total of 144 female rats selected randomly for the experiment, with twelve in each cell of the factorial design.

The experiment comprised two phases. In the first phase, during four successive days in early, mid- or late pregnancy, each gravid female was given subcutaneous dorsal injections of one of the three drugs or distilled water. Injections were given to each animal three times a day, at 8 a.m., 4 p.m. and 12 p.m. Drugs were freshly prepared every 48 h and administered in the following daily doses: reserpine, 0.1 mg/kg; chlorpromazine, 6.0 mg/kg; and meprobamate, 60.0 mg/kg. The solutions used were so adjusted that animals of equal weight would receive an equal volume of fluid (including animals receiving water only) and were as follows: reserpine, 0.0017 per cent; meprobamate, 1.0 per cent; and chlorpromazine, 0.1 per cent. Animals in "early" pregnancy (I) were injected on days 5-8, those in "mid-" pregnancy (II) on days 11-14, and those in "late" pregnancy (III) on days 17-20. The offspring were weaned at 21 days of age and placed in large community cages until they were 84 days old. In the second phase of the experiment, animals were weighed at age 84 days and conditioned avoidance training was begun. Animals were given twenty trials per day of conditioned avoidance training until a criterion of seven out of eight successive correct avoidance responses was achieved. The rat was placed in one side of a shuttle box (5 in.  $\times$  5 in.  $\times$  10 in.) which was completely dark. The experimenter opened the door, which automatically turned on a light and sounded a buzzer. If the rat did not go into the goal box within 5 sec, a 0.6 m.amp shock was administered for 0.75 sec. The trials for each rat were run consecutively, with an interval between trials of about 10 sec. On the day after the acquisition criterion was reached, extinction training was begun. Each animal was given twenty trials per day of extinction training, which was identical to the acquisition training except that the shock was disconnected. The criterion for extinction was seven out of eight successive failures to give a conditioned avoidance response.

The mean weight at 84 days is shown for each group in Table 1. The analysis of the weight results showed significant effects ( $P < 0.001$ ) of drug administration depending on the period of administration. In group I, the control animals weighed significantly more than Res animals and Chl and Mep animals weighed significantly more than both control and Res animals. No differences were found in group II. In group III, control animals weighed significantly more than Mep animals and Chl animals weighed significantly more than all other subgroups. The analysis of variance also showed a significant overall effect of the drug, the Chl animals weighing significantly more ( $P < 0.001$ ) than all the other groups. All post-analysis of variance tests were done using the Duncan range test<sup>2</sup>.

The score for conditioned avoidance acquisition was the number of trials taken to reach the criterion. These means are shown in Table 2. Analysis of variance indicated a significant effect only in the drug/period interaction ( $P < 0.05$ ), caused by the fact that the Mep II group was significantly slower in acquisition than control II and Chl II groups and that Chl III animals were significantly slower than control III animals. No other differences within periods were significant.

The score for conditioned avoidance extinction was the number of trials taken to reach the criterion. These means are shown in Table 3. Analysis of variance indicates

Table 1. MEAN WEIGHT IN GRAMS AT 84 DAYS

	Stage of pregnancy when drug administered			Mean
	I	II	III	
Control	224	232	229	229

Table 2. MEAN TRIALS TO ACQUISITION CRITERION

	Stage of pregnancy when drug administered			Mean
	I	II	III	
Control	14.7	12.2	11.0	12.6
Meprobamate	12.3	18.3	11.8	14.2
Chlorpromazine	14.6	11.4	15.7	13.9
Reserpine	11.1	14.5	13.9	13.2

Table 3. MEAN TRIALS TO EXTINCTION CRITERION

	Stage of pregnancy when drug administered			Mean
	I	II	III	
Control	43.5	89.5	113.3	82.0
Meprobamate	55.3	54.4	53.3	54.4
Chlorpromazine	63.1	64.5	58.1	61.9
Reserpine	111.8	75.9	50.5	79.4

a significant effect ( $P < 0.05$ ) of the drug administered, with both the Chl and Mep animals extinguishing more rapidly than the control animals. The drug/period interaction was also significant ( $P < 0.001$ ), comparisons within periods of administration showing that in period I all groups extinguished faster than the Res animals, in period II the Mep animals extinguished faster than control animals, and in period III all drug groups extinguished more rapidly than the control group. The speed of extinction is usually considered to be an inverse function of the strength of the conditioning.

These results show conclusively that the administration of tranquillizing drugs to pregnant rats affects the weight and the acquisition and extinction of a conditioned avoidance response. As would be expected from previous research<sup>1,3</sup>, the effect depends on the drug used and the period of pregnancy in which it is administered. Weight scores, presumably reflecting general health, are adversely affected by administration of reserpine in period I or meprobamate in period III. The rate of acquisition of the conditioned avoidance response is adversely affected by administration of meprobamate in period II or chlorpromazine in period III. The extinction rate is adversely affected by the administration of reserpine in period I, meprobamate in period II, and chlorpromazine, meprobamate or reserpine in period III.

The exact findings of this experiment differ somewhat from previous research<sup>1,4</sup>, as would be expected from the fact that an aversive response was used instead of a mild appetitive response. In all likelihood, performance in avoidance conditioning involves considerable emotional components in addition to learning ability. Also, the strain of rats used for this research was somewhat larger and healthier than in previous work. The general conclusion from all these studies is inescapable, however: the administration of tranquillizing drugs to gravid rats produces adverse health and learning effects in the offspring. All the drugs used had some adverse effect, depending on the period of administration, and none was uniformly deleterious. The implications of the use of such drugs by pregnant women clearly need to be examined.

### Animal Model of Viral Oncogenesis

ELECTRON microscopy showed a virus in the tissues of a strain of guinea-pigs in which leukaemia arose spontaneously. This strain of guinea-pigs dates back to 1906 when inbreeding began at the Bureau of Animal Industry of the US Department of Agriculture<sup>1</sup>. We are at present using one of these families, now known as strain No. 2, in our research. In 1940, these animals were transferred to the National Cancer Institute where inbreeding of this strain has continued until now. A high degree of genetic homogeneity has resulted from this method of breeding. In 1954, Congdon and Lorenz reported several forms of acute lymphatic leukaemia<sup>2</sup>. Ten transplantable tumours were found, and of these four were carried and three were subsequently lost.

Electron microscopy of animals carrying this transmissible leukaemia has revealed a new virus. The leukaemia is at present being transmitted with cell-free leukaemic material, such as plasma or tissue extracts, prepared by repeated ultracentrifugation at speeds up to 40,000 r.p.m. The infective agent crosses the placental barrier in the leukaemic mother and has been recovered from the gastrointestinal and urinary tracts. Feeding leukaemic spleen cells has also produced the disease. Lines of guinea-pigs other than strain No. 2 are almost entirely resistant; but the disease can be serially propagated, with a 100 per cent mortality rate, in  $F_1$  hybrids originating from cross-mating susceptible strain No. 2 animals with resistant Hartley guinea-pigs.  $F_1$  hybrids, irrespective of age, are now used exclusively. After injection by various routes, the disease has an average incubation period of 18 days and ends in death with blast cell counts in the peripheral blood up to 350,000 cells/mm<sup>3</sup>. Autopsy shows widespread leukaemic involvement of the entire haematopoietic apparatus<sup>3</sup>. The leukaemia is of special interest because the experimental disease resembles the human disease very closely in its haematological and pathological responses. Tissues from animals in the terminal stages of acute leukaemia were examined with light and electron microscopes. Viral particles could readily be demonstrated in plasma pellets, lymphoid tissue and megakaryocytes in all animals examined<sup>4</sup>. Control animals had no particles.

The guinea-pig leukaemia virus is about 85 m $\mu$  in diameter. It resembles the type C particles associated with murine leukaemia but differs in detail. The virus is smaller and the intermediate layer is not as electron dense (Fig. 1). The virus particles can be seen to bud into the cisterna of the endoplasmic reticulum (Fig. 2). The particles were present in high-speed plasma pellets, bone marrow, spleen

Fig. 1. Section of part of a cell from the bone marrow of a leukaemic guinea-pig. The particle can be seen budding from membranes of the endoplasmic reticulum. ( $\times c. 142,500$ .)

Fig. 2. Particles present in a plasma pellet from a leukaemic guinea-pig. ( $\times c. 86,700$ .)

and lymph node biopsies when the guinea-pigs had peripheral white counts of more than 100,000 cells/mm<sup>3</sup> (ref. 5). Light microscope examination showed that almost all organs had been infiltrated by neoplastic lymphoblasts. This virus is destroyed by exposure to ultra-violet light or X-rays, by heating for 30 min at 56° C, by shaking with ether or acetone and by formalinization. The virus is resistant to trypsin. The infectivity of leukaemic spleen cell suspensions treated with glycerine and calf serum can be preserved by storing them at -90° C for up to 5 months.

Leukaemia in guinea-pigs appears to be limited to this strain and associated with the presence of viral particles. Virus recovered from the blood of guinea-pigs with induced leukaemia, using resuspended pellets obtained by ultracentrifugation, has induced leukaemia when injected into susceptible guinea-pigs. We have found that the virus acts as a potent antigen in homologous host species. It seems that a new animal model system for work in viral oncogenesis has been opened up by the demonstration of a new viral leukaemia in a strain of inbred guinea-pigs.

### Recognition of the Individuality of Tumour Strain by Sensitized Peritoneal Lymphoid Cells

Odashima<sup>1</sup> and Yoshida<sup>2</sup> have demonstrated the biological individuality of more than fifty different strains of rat ascites hepatomata. Even in strains originating from the same animal, there are marked differences in the pattern of growth as well as differences in such cytological characters as chromosome constitution or sensitivity to anti-tumour agents<sup>3</sup>. Antigenic differences among these strains have not, however, been investigated.

Over the past 2 years, four different strains of ascites hepatoma, AH-64A, AH-64B, AH-64C and AH-64D, and six sub-strains have been established, all of which originated from primary tumour ascites or separate hepa-

Table 1

Hepatoma strain	Transfer generations	Modal No. of chromosomes	Islands in tumour ascites (per cent)	Tumour take (per cent)	Mean survival (days)
AH-64A	90	66	1.0	100	14.0
AH-64B	90	71	83.0	100	14.5
AH-64C	100	81	5.0	100	10.5
AH-64D	90	72	7.0	100	11.5

toma nodules in an individual female Donryu rat fed 0.05 per cent 3'-methyl-4-dimethylaminoazobenzene (3'-Me-DAB) for 5 months. They have been maintained by intraperitoneal passage in isologous Donryu rats that have had their genetical homogeneity checked by intrastrain skin grafting<sup>4</sup>. The biological characteristics of the first four strains, shown in Table 1, are individually distinctive. The Donryu rats are quite susceptible to all these tumour strains and 100 per cent tumour takes were recorded in the twenty most recent transfer generations. AH-64B is the only strain which has many "hepatic islands", that is, small or large clusters of tumour cells.

When the Donryu rats were immunized with tumour cells previously attenuated with nitrogen mustard N-oxide ('Nitromin'), they acquired a marked resistance to further transplantation of the tumour strain used for immunization<sup>5</sup>. The percentage of animals that developed a resistance for AH-64A, AH-64B, AH-64C and AH-64D tumours was 38.7, 82.4, 36.5 and 27.3 respectively. This may have been due to differences in the immunizing capacity of the individual tumour strains. Sensitized peritoneal lymphoid cells from each group of resistant animals were pooled and separated by centrifugation into supernatant and cell fractions. The cell fraction was washed with glucosol solution and adjusted to a suspension of  $10^7$  cells/ml. Lymphoid cells from normal intact rats or from rats sensitized with normal rat liver cells were also prepared to serve as controls. An equal volume of a viable tumour cell suspension containing  $10^5$  cells/ml. of each tumour was then added to the separate fraction, and incubated at 37° C for 15 min. The ratio of the number of lymphoid cells and the number of tumour cells was made constant in every case at 100:1. After incubation, 1 ml. of the mixed cell suspension was inoculated intraperitoneally into five to sixteen intact female rats of 80-100 g body weight. Table 2 shows that the mean survival time, when half the host animals were killed by the progressive accumulation of tumour ascites, was markedly prolonged only when the tumour cells were mixed with lymphoid cells. Moreover, as indicated by the percentage increase in the survival time of the hosts, the differences between the effects of the cell-free and cell fractions were most marked when the tumour cells were exposed to sensitized lymphoid cells obtained from animals resistant to the corresponding tumour strain. The tumour strain-specific reaction of the sensitized lymphoid cells seemed to be relatively mild when AH-64B cells were used. In addition the growth of this strain was inhibited only slightly when the cells were exposed to lymphoid cells sensitized with other tumour strains or normal liver tissue.

Differences in antigenic specificity and immunogenicity between individual tumours produced in a single animal have been reported by a few workers. Globerson and Feldman<sup>6</sup> have shown that each of two sarcomata produced in a mouse by simultaneous applications of benzo-pyrene had distinct antigenic specificity. Rosenau and Morton<sup>7</sup> have pointed out that spleen cells sensitized with each of a pair of sarcomata induced by methylcholanthrene in the same mouse showed an inhibitory effect only on the corresponding tumour, both *in vivo* and *in vitro*. Similar results were obtained by Baldwin<sup>8</sup> on rat liver carcinomata induced by 4-dimethylaminoazobenzene. He found that the sensitized peritoneal lymphoid cells only prevented the growth of the tumour used for immunization when they were inoculated together with the tumour cells into intact animals.

From the present experiment it must be emphasized that four different strains of ascites hepatoma induced by 3'-Me-DAB in the same animal showed marked differences in their antigenic as well as morphological characteristics, and that the peritoneal lymphoid cells sensitized with each tumour strain could react specifically with the corresponding tumour strain used for immunization.

### Increased Tumour Induction by Adenovirus Type 12 in Thymectomized Mice and Mice treated with Anti-lymphocyte Serum

TUMOURS<sup>1</sup> have been induced in three out of thirteen C3Hf/Gs mice inoculated neonatally with adenovirus type 12; no tumours were seen in inoculated DBA/J or A/J mice. Tumours<sup>2</sup> have been seen in C3H/HeN and BALB mice only after surgical thymectomy, and there is evidence<sup>3,4</sup> that tumours induced by adenovirus type 12 in mice have a specific antigen which elicits in the host a cell-mediated, homograft type immune response. The marked depression of cell-mediated immunity after thymectomy presumably accounts for the increased tumour formation after this procedure<sup>5</sup>; this is observed after neonatal exposure to those viruses that do not induce tolerance (that is, with polyoma, SV40 and adenovirus)<sup>6</sup>.

Experiments with immunosuppressants have provided important information about the role of immune responses in controlling tumour induction and growth<sup>6,7</sup>, and it is

Table 2

useful to have at our disposal effective immunosuppressants that work in different ways. The use of antiserum against lymphoid cells (ALS), which has been shown to prolong greatly the survival of skin grafts in adult mice across an H-2 barrier<sup>8-10</sup>, has aroused some interest. We therefore decided to examine the effects of this antiserum on the induction of tumours by viruses. Antisera were prepared in rabbits of the New Zealand strain by two intravenous injections of  $10^9$  thymus cells from *CBA* mice at an interval of 14 days and bleeding 7 days after the second injection. Before use sera were decomplexed by subjecting them to a temperature of  $56^\circ\text{C}$  for 20 min, and they were absorbed with washed *CBA* mouse erythrocytes until there was no further agglutination.

Fifteen newborn *CBA* mice were injected subcutaneously with 0.05 ml. of adenovirus type 12 (strain 1131, isolated and propagated in human embryonic kidney cells, with a titre of  $10^{7.2}$  TCD<sub>50</sub>/ml.). The mice were given 0.05 ml. of ALS on the day after birth and 0.1 ml. of this antiserum on the eighth and fifteenth days. A second group of twelve mice was given the same inoculum of adenovirus on the day of birth and surgically thymectomized 2 days later. A third group of twenty-four controls received virus alone subcutaneously on the day of birth. The cumulative incidence of tumours is plotted in Fig. 1. Most control mice developed tumours between 3 and 8 months after inoculation of virus. Thus the *CBA* strain is more susceptible to adenovirus oncogenesis than other strains so far tested. Some acceleration of tumour formation was observed in mice treated with ALS or thymectomized, but the effect was not marked and does not attain formal statistical significance. This result suggests that the relatively long latent period for tumour induction by adenovirus in mice is caused chiefly by factors other than the immune response of the host.

Another experiment was carried out with a much smaller virus inoculum (approximately 100 times less than the first). Only one of the twenty-four controls developed a tumour, whereas nearly half the twenty-four mice receiving ALS or thirteen thymectomized mice developed tumours (Fig. 2). The differences between these two groups and the controls were very significant ( $P \approx 0.01$ ). Although the tumours began to appear sooner after treatment with ALS than after thymectomy, the differences

Fig. 1. Appearance of tumours after inoculation of newborn *CBA* mice with a large dose of adenovirus type 12.

Fig. 2. Appearance of tumours after inoculation of newborn *CBA* mice with a small dose of adenovirus type 12.

between the two treated groups are not statistically significant.

A third experiment was carried out using 0.05 ml. of undiluted adenovirus type 12 in *C3H/He* mice. At the time of writing, 6 months later, nine out of twelve mice treated with ALS have developed tumours whereas no tumours have appeared in controls (Fig. 3). This potentiation is very significant ( $P < 0.001$ ) and even more marked than that seen by Kirschstein *et al.*<sup>2</sup> after thymectomy.

In all experiments tumours appeared subcutaneously, at the sites of inoculation, and had the histological appearances characteristic of tumours induced by adenovirus<sup>1,4</sup>. Some of the *CBA* tumours contained antigen reacting specifically in complement-fixation tests with sera from hamsters bearing tumours induced by adenovirus 12. Sera of tumour-bearing mice contained no haemagglutination-inhibiting antibodies against polyoma virus. In experiments with adenoviruses in mice polyoma virus must be excluded, for the two have a synergistic effect on oncogenesis<sup>11</sup>.

The results show that ALS administered in relatively small doses to newborn mice increases tumour induction by small doses of adenovirus 12 in a susceptible strain of mice (*CBA*) or by a large dose of adenovirus 12 in a relatively resistant strain of mice (*C3H*). These effects are presumably caused by the decreased efficiency of cell-mediated immune responses after administration of ALS. In keeping with this view are recent findings of Jooste (personal communication) that injections of ALS in *CBA* mice on the day of birth and day 11 greatly prolong survival of skin grafted across an H-2 barrier on day 21. It has also been found<sup>12</sup> that delayed hypersensitivity to protein antigens is abolished or depressed by injections of ALS into newborn mice. Injections of rabbit antisera prepared in a different way against rat thymus were reported by Anigstein *et al.*<sup>13</sup> to increase the size of sarcoma 180 implants subsequently made in mice. Although these tumours are not known to contain specific antigens, they could have been antigenic through carriage of viruses or for other reasons. Thus the potentiation of sarcoma growth may have been caused by the immunosuppressant effects of anti-thymus serum rather than by stimulation of tumour growth itself.

Usually the use of ALS has certain advantages over surgical thymectomy. The dosage and timing of the immunosuppressant effect can be better controlled with

Fig. 3. Appearance of tumours after inoculation of newborn C3H/He mice with a large dose of adenovirus type 12.

antisera, and simple injections are easier than surgery, especially with hamsters and rabbits. Doses of ALS that do not produce runtting are sufficient to potentiate tumour formation. The effectiveness of relatively small doses of antiserum in newborn animals may be the result of induced immunological unresponsiveness of the recipients to the rabbit  $\gamma$ -globulins involved, which allows the latter to exert a prolonged action. Furthermore, when antisera are used, the thymus is left *in situ*, which may be important in certain cases, notably with the leukaemias, in which the thymus is a target organ for oncogenic viruses. Further experiments along these lines have given promising results which will be presented for publication shortly.

### Iron Resorption in Fish-induced Anaemia in Mink

ANAEMIA is a common condition in mink kits and may cause serious economical losses, for the development of good quality fur depends on a normal haemoglobin concentration in the blood. Anaemia in mink induced by fish leads to achromotrichia, cotton fur, and may be described as a hypochromic microcytic iron deficiency anaemia.

The particular anaemic condition considered in this investigation occurs when the dietary protein for kits consists mainly of raw fish such as whiting (*Gadus merlangus*), coalfish (*Gadus virens*) and hake (*Merluccius vulgaris*). The percentage of kits which develop anaemia, however, varies widely<sup>1-5</sup>.

Development of anaemia and light underfur can be prevented by replacing the raw fish in the diet with boiled fish of the same species. Supplementing the diet of raw fish with vitamins and trace elements in the growing period failed to give any response<sup>3,6</sup>.

There are two fundamental routes through which this form of anaemia may develop: (1) the absorption of iron from the intestine into the intestinal mucosa may be obstructed; (2) the transport of iron from the intestinal mucosa to the iron stores and to the haemoglobin synthesizing tissues may be disturbed or reduced in one or more steps.

We have studied the absorption of iron in mink kits fed raw and boiled coalfish, to discover how and where the disturbances take place. We have used the iron isotope <sup>59</sup>Fe as a tracer. Comparative studies were performed with anaemic and non-anaemic animals.

Iron absorption studies were made on animals which had become anaemic after a diet of raw fish. The animals which were tested with boiled fish were fed this diet 2 days before the administration of iron.

All experiments were carried out with two animals in each series, one fed raw and the other boiled fish. A dose of 6  $\mu$ c. ferrie <sup>59</sup>Fe was administered, as suggested by preliminary studies, together with 1.5 mg inactive ferrie iron as a carrier, all in a volume of 15 ml. The solutions were slightly acidic (HCl) and were administered through a stomach tube. A blood sample from the tail vein was transferred to a counting plate, weighed and air-dried.

The weight of blood samples was kept at approximately 0.5 g, which gave a reasonable counting rate from a thin film of blood. The dry blood was tested with a Geiger-Müller tube, and the activity is given as c.p.m./g blood. To keep the error due to self-absorption at a minimum, the weights of the blood samples were kept as equal as possible, within the limits of 0.48–0.52 g. To see whether there was a good proportionality between sample weight and activity within these limits, a curve was drawn, giving the counting rate as a function of weighings of one active blood sample. A fairly good proportionality was found (Fig. 1) and the activities of the blood samples

Fig. 1. Activity of different sample sizes of one active blood sample.

Table 1a

	Animal No.	Hb (per cent)	Cell volume (per cent)	Date of tracer application	Dates of collecting and counting rate of blood samples (c.p.m./g)						
					1/4	28/4	2/5	12/5	19/9	21/9

	192	16.6	57	26/4	32	33	30				
	231	18.5	57	18/5				164	161	157	
	164	19.2	63	18/5				100	105	111	

could be recalculated to 0.50 g weighings without introducing errors worth mentioning.

The results of these experiments are given in Table 1a. Only a few of the measurements are given in the table, but none of the other readings gave controversial results. The table reveals that in anaemic animals the absorption of iron into the blood stream is higher in animals fed boiled coalfish than in the animals fed raw fish.

Table 1b shows the results from corresponding experiments with non-anaemic, normal animals. In this case the particular differences with respect to iron absorption are not observed.

The experiments seem to indicate an impediment to iron absorption. It is still possible, however, that iron may pass into the intestinal mucosa and be stored there as ferritin but that the transport of iron from ferritin to the blood is obstructed by one or more substances simultaneously absorbed from the fish. Martinssons<sup>6</sup> studied the iron absorption in anaemic animals previously fed raw fish and found that they readily absorbed iron when dosed on an empty stomach.

In order to study the absorption into the intestinal mucosa, four of the anaemic experimental animals were killed, and 1 cm long pieces were cut from their intestines at 10 cm intervals. These tube-shaped pieces were split, and the inner intestinal walls washed with water, care being taken not to destroy the mucosa. The different pieces were thereafter air-dried, weighed and tested with a Geiger-Müller tube. The results are set out in Table 2, calculated as c.p.m./g dry tissue. The activities of some organs are also given, calculated on the same basis. With respect to self-absorption, the same precautions as for blood were taken. These results also reveal a pronounced difference in iron absorption between anaemic animals fed boiled fish and those fed raw fish. The sections close to the stomach show the highest activities.

From the measured activities in the intestines, it is reasonable to conclude that part of the iron, under the

influence of one or more factors in the raw fish, is not absorbed but remains bound in the fish material.

### Tyrosinase Activity in the Amelanotic Melanoma in Golden Hamsters

It is known that active tyrosinase (*o*-diphenol : O<sub>2</sub> oxidoreductase) occurs in melanotic melanoma; however, its presence in the amelanotic variety of these tumours is still controversial. Tyrosinase activity in pigmented melanomata was detected and investigated by means of the Warburg manometrical method using tyrosine and dihydroxyphenylalanine (DOPA) as substrates for the enzyme<sup>1,2</sup>. To the best of our knowledge, however, when this method has previously been used to investigate amelanotic melanomata, it has failed to detect any tyrosinase activity<sup>3,4</sup>. Other methods used for studying these tumours have given disparate results<sup>5-10</sup>. For this reason we decided to use the manometrical method of Warburg to investigate amelanotic melanomata in hamsters, which have previously been described, on the basis of histochemical investigations, as "tyrosine-positive".

This tumour occurred in 1962 as a result of a spontaneous transformation of a transplantable melanotic melanoma and has since been maintained by serial passages. The properties of both related tumour lines have been described elsewhere<sup>8,11</sup>.

The transplants of the amelanotic melanoma used in the present investigations belonged to the passages consecutively numbered 25 to 29. Thirty tumours were used for assays. One month after subcutaneous implantation, transplants which measured 3-5 cm in diameter were removed and their tissue was separated from necrotic masses. The tissue was frozen and kept at -15° C for use within the next 2 weeks (we have observed that after this period a gradual decrease in activity occurs). Immediately before measurements were made, the tissues of two or three tumours were joined together and mixed with 0.1 molar phosphate buffer, pH 6.8 (10 g of frozen tissue/100 ml. of buffer). The mixture was then homogenized at 0° C and 14,000 r.p.m. Tyrosinase activity was determined in the homogenate thus prepared as well as in the sediment and the supernatant obtained from it by centrifugation at 18,000g for 10 min. Before any measurements were made, the sediment was washed with buffer, centrifuged once more and resuspended in a quarter of the volume of buffer originally used.

Table 2

	Animal No.	Date of tracer application	Date of death	Vena portae blood	Liver	Kidney	Spleen	Counting rate (c.p.m./g)						Ash of intestine	Femoral marrow
								Intestine, close to stomach	Intestine, 20 cm from stomach	Intestine, 40 cm from stomach	Intestine, 60 cm from stomach	Intestine, 80 cm from stomach	Close to rectum		
Boiled fish	122	27/4	3/5	503	200	134	506	58	61	47	55	80	49	20	182
	106	9/5	12/5	—	60	69	197	85	40	26	9	8	13	8	—
Raw fish	123	27/4	3/5	74	24	32	51	34	28	0	0	9	0	3	95
	376	9/5	12/5	—	35	43	311	23	25	0	0	0	17	7	—

The substrates used were *dl*-DOPA and *l*-tyrosine. The inhibitors were sodium diethyldithiocarbamate (DIECA) and hydroxylamine. The uptake of oxygen was measured in a Warburg apparatus according to the method devised by Lerner *et al.*<sup>12</sup> (37° C, pH 6.8). 1.3 ml. of a preparation from the neoplastic tissue and 1.0 ml. of 0.1 molar phosphate buffer were added to the main compartment of the Warburg flask. 0.2 ml. of a 10 per cent solution of potassium hydroxide was then added to the central well. 0.5 ml. of the solution of one of the substrates (DOPA at a concentration of 6 mg/0.5 ml. of water, or tyrosine at a concentration of 0.45 mg/0.5 ml. of water plus trace amounts of DOPA) was placed in the sidearm. If the inhibitors were used, 0.3 ml. of them was added to the main compartment in place of an equal volume of buffer (the concentration of DIECA was 10<sup>-3</sup> moles/l. and that of hydroxylamine was 10<sup>-2</sup> moles/l.). The uptake of oxygen was read during the first hour of measurement and the results were expressed as  $Q_{O_2} = O_2$  uptake in  $\mu$ l./h/mg of protein. The content of protein was determined by the Kjeldahl method.

For comparative purposes we assayed, under the same conditions, homogenates of the melanotic melanoma as positive controls and homogenates of liver and kidney from normal hamsters as negative controls.

The results given in Table 1 were obtained after corrections had been made for the endogenous respiration. Each value represents a mean of three measurements performed for the same preparation.

Table 1. COMPARISON OF TYROSINASE ACTIVITY AGAINST DOPA AND TYROSINE OF PREPARATIONS OF THE AMELANOTIC MELANOMA, MELANOTIC MELANOMA, LIVER AND KIDNEYS

Material and preparation	Substrate			Substrate		
	$Q_{O_2}$	DOPA Inhibition by hydroxylamine (per cent)	DOPA Inhibition by DIECA (per cent)	$Q_{O_2}$	Tyrosine Inhibition by hydroxylamine (per cent)	Tyrosine Inhibition by DIECA (per cent)
Amelanotic melanoma, homogenate	3.5	54.5	100.0	1.4	35.0	100.0
Amelanotic melanoma, sediment	3.0	50.0	100.0	1.7	29.0	100.0
Amelanotic melanoma, supernatant	7.8	49.0	100.0	4.4	77.0	100.0
Melanotic melanoma, homogenate	28.0	36.0	98.0	20.0	88.0	100.0
Liver, homogenate	2.1	74.0	75.0	—	—	—
Kidneys, homogenate	2.2	66.0	71.5	—	—	—

It can be seen from Table 1 that the preparations from the amelanotic melanoma oxidize tyrosine and DOPA and that this is completely inhibited by DIECA. These findings demonstrate that in the amelanotic melanoma studied tyrosinase activity is present in an amount detectable by the manometric method. The level of activity, however, is significantly lower than that in the melanotic tumour. The partial inhibition of oxidation by hydroxylamine and the activity against DOPA observed in the homogenates of the liver and kidneys indicate that non-specific oxidases also contribute to the uptake of oxygen. During the determinations of oxidase activity against tyrosine in the homogenates of the liver and kidney the gas liberated as a result of side-reactions exceeded the eventual oxygen uptake and rendered the calculation of  $Q_{O_2}$  impossible. Tissue preparations of the amelanotic melanoma obtained by homogenization at less than 13,000 r.p.m. did not reveal any tyrosinase activity.

In the course of our measurements, we observed a gradual darkening of the reaction mixtures containing preparations of the amelanotic melanoma and tyrosine or DOPA. The homogenates of the liver and kidneys developed no pigmentation in the presence of tyrosine and slight pigmentation only when mixed with DOPA. The homogenates of the melanotic tumours were always black in colour.

The next experiments suggested that the tyrosinase activity in the material from the amelanotic melanoma may be increased by incubation with trypsin according to the method used by Trojanowski and Szarkowski<sup>13</sup>. The homogenates of the tumour tissue were centrifuged at 18,000g and the sediments were resuspended in 0.05 molar phosphate buffer (pH 7.8). The suspensions were incubated for 18 h at room temperature with trypsin at a concentration of 0.25 per cent and in the presence of antibiotics (2,000 units of penicillin and 2,000 $\gamma$  of streptomycin). After incubation the activity, as measured against tyrosine and at pH 6.8, appeared to have increased in comparison with the control samples by 50 per cent for the whole suspension and by 30 per cent for the supernatant obtained after centrifugation of the suspension. The level of tyrosinase activity in the amelanotic melanoma was low compared with that in melanotic tumour and it seems likely that this is due in part to the presence of a specific inhibitor which can be removed by the digestion with trypsin. Trypsin, however, does not restore the full tyrosine activity in the tissue examined. This suggests that other factors such as the repression of the synthesis of the enzyme protein or other inhibitors may play a part in the loss of the ability of amelanotic melanomata to produce melanin.

### Disturbed Proliferation of Erythropoietic Cells in Pernicious Anaemia

THERE is considerable evidence that in many types of mammalian cells DNA synthesis (*S*) occupies only a part of the intermitotic time. In diploid cells the *S* period is preceded by an interval of time (*G*<sub>1</sub>) when the nucleus has a 2c DNA content and is followed by a pre-mitotic interval (*G*<sub>2</sub>) when the nucleus has a 4c DNA content<sup>1,2</sup>. Conventional autoradiography of a cell population labelled briefly with tritiated thymidine can show the cells in *S*, but it is not possible to be certain whether an unlabelled cell is in *G*<sub>1</sub> or *G*<sub>2</sub>. This difficulty can be overcome when autoradiography is combined with quantitative cytochemical measurement of the DNA content<sup>3</sup>. Furthermore, this technique can be used to examine cells the morphology of which has been identified using classical staining techniques<sup>4</sup>. We have used this technique in the investigation of the relation of the morphology of

erythropoietic cells and their position in interphase. The distribution in normal bone marrow has been compared with that in severe pernicious anaemia to locate the site in the maturation sequence at which ineffective erythropoiesis becomes predominant.

Freshly aspirated bone marrow was labelled *in vitro* with 1–3  $\mu$ c. of tritiated thymidine/ml. for 30 min at 37° C. The bone marrow fragments were smeared and stained by the May–Grünwald–Giemsa method and photographic maps prepared. The position and type of the erythropoietic cells were recorded. Erythroid cells were classified morphologically into pronormoblasts, basophilic normoblasts and polychromatic normoblasts according to nuclear size and structure and the tinctorial characteristics of the cytoplasm. Polychromatic cells have been sub-divided into early cells capable of division and late non-dividing cells. The stain was leached out and the preparation was re-stained by the Feulgen method. The absorbance of the Feulgen stained nuclei was measured with a Deeley pattern microdensitometer<sup>5</sup> and the cells in *S* were identified by autoradiography.

In normal erythropoiesis both pronormoblasts and basophilic normoblasts were observed in all stages of interphase. Thus we cannot support Lajtha and Oliver<sup>6</sup>, who suggested that the basophilic normoblast is the 2c and the pronormoblast is the 4c stage of one cell cycle.

On examination the data showed that the percentage of pronormoblasts in *G*<sub>1</sub>, *S* and *G*<sub>2</sub> was similar to the percentage of basophilic normoblasts in these compartments of interphase. The results for pro-erythroblasts and basophilic erythroblasts have therefore been grouped together. The relative distribution of erythropoietic cells in the different phases of the cell cycles in normal bone marrows is shown in Table 1. Among 638 nuclei of basophilic cells, only one unlabelled cell was observed with a DNA content clearly outside the normal range for the spread about the 2c and 4c modes.

Table 1. PERCENTAGE DISTRIBUTION OF ERYTHROPOIETIC CELLS IN THE VARIOUS PHASES OF INTERPHASE

34	60	6	<1	10.0	638	9	82	9	490

Combined results for three normal marrows. Column *U* represents unlabelled cells with DNA contents lying between the 2c and 4c values.

The point of change in the morphology of a polychromatic cell that indicates that it can no longer undergo further division cannot be defined precisely at present. The point of cut-off between the dividing early polychromatic cells and the non-dividing late polychromatic cells was therefore based on an arbitrarily selected nuclear size. This method showed that cells classified as late polychromatic cells had a 2c DNA content. It must be emphasized that this point of cut-off between the dividing and non-dividing compartments was quite arbitrary and that small changes in the criteria defining the cut-off point would significantly alter the percentages of early polychromatic cells in *S* and *G*<sub>2</sub>. On the other hand, there is no doubt that those polychromatic cells that were in *S* or *G*<sub>2</sub> are part of a dividing population. The ratio *S/G*<sub>2</sub> is therefore a more reliable parameter of the dividing polychromatic compartment, because it is unaffected by any uncertainty in morphological classification.

Fig. 1. The distribution of Feulgen absorption values for cells not labelled with tritiated thymidine.

In untreated pernicious anaemia there was evidence of a departure from the normal cell kinetics. The pattern of the abnormality remained constant although its severity varied from patient to patient. Table 2 shows the relative distribution of cells in different phases of the cell cycles in five cases of pernicious anaemia. The significant feature emerges that there was a decreased *S/G*<sub>2</sub> ratio in the early polychromatic megaloblasts caused by a relative increase in the number of cells in *G*<sub>2</sub> and there was an increased proportion of unlabelled cells with DNA contents that were between the 2c and 4c modes. These changes were less pronounced in the promegaloblasts and basophilic megaloblasts. Fig. 1 shows a histogram of the distribution of the DNA contents of unlabelled early polychromatic cells in a marrow from a normal subject and in a patient with pernicious anaemia. This increase of cells in *G*<sub>2</sub> in pernicious anaemia has been previously reported by Menzies *et al.*<sup>7</sup>, who did not identify the cell types concerned and did not focus their attention on the relation between the perturbation of the cell kinetics and the cell maturation.

Our findings taken independently suggest several interpretations, but complementary information is available from an investigation of erythropoietic cell kinetics in patients with pernicious anaemia, after *in vivo* labelling with tritiated thymidine. Cronkite *et al.*<sup>8</sup> have shown that the number of non-dividing polychromatic cells (*E*<sub>5</sub> cells) produced each hour/1,000 proliferating erythropoietic precursors was significantly lower than normal in two cases of pernicious anaemia. Flidner *et al.* (personal communication) have demonstrated a disappearance of erythropoietic cells which was maximal in the dividing polychromatic cell compartment (*E*<sub>4</sub>). It seems reasonable to assume that the loss of cells detected by these

*in vivo* investigations is directly related to the failure of DNA synthesis and the build-up of cells in  $G_2$  shown in Table 2. It would appear, therefore, that the death of these arrested cells is responsible for the ineffective erythropoiesis seen in megaloblastic anaemia caused by vitamin  $B_{12}$  deficiency<sup>9,10</sup>.

## Inhibition of Fatal Anaphylaxis in Mice inoculated with a Virus-induced Leukaemic Tumour Extract

THE salutary effect of intensive parenteral treatment with erythropoietin-containing rabbit serum in mice infected at 2 days of age with a leukaemia virus has been reported<sup>1</sup>. During the investigation ten of twenty-two mice that developed signs of neoplastic disease as determined by palpation of spleen and lymph nodes later showed evidence of regression of these phenomena. To exclude the possibility that the splenomegaly and lymphadenopathy were a hyperplastic response to repeated inoculation of a foreign antigen, the effect of rabbit serum on uninfected mice was tested using the same regimen as that used for infected mice. Splenomegaly and lymphadenopathy were minimal and transient in these circumstances, but a proportion of the uninfected mice died from anaphylactic shock during the course of treatment whereas infected mice did not. The present communication is concerned with this observation.

Inbred *BALB/c* mice were randomly bred. The  $F_1$  progeny were inoculated when 2 days old (except where noted) subcutaneously and intraperitoneally, 0.05 ml. at each site, with 10 per cent cell-free extracts of neoplastic spleens either directly virus-induced or after 110 transplant generations. The virus-induced disease was obtained in 1958 in *BALB/c* mice inoculated when newborn with a cell-free extract of the Ehrlich ascites tumour<sup>2</sup>. At that time it was considered to be primarily a reticulum cell sarcoma; cases of lymphosarcoma, however, also occasionally appeared. The average latency of the disease was eventually reduced from about 1 yr to 3 months, and lymphosarcomata were no longer seen. A continuing investigation of its cytopathology is in progress<sup>3,4</sup>. As a result of these investigations it appears more appropriate now to refer to the leukaemia as a myeloproliferative syndrome, exhibiting either (or both) abnormal myeloid or erythroid differentiation.

The extracts were prepared from spleens which had been stored in a carbon dioxide freezer as follows: after thawing, the tissue was suspended in phosphate buffered saline and homogenized for 2.5 min at the fastest speed of the 'Virtis 45' (45,000 r.p.m.) apparatus in a vessel surrounded by ice; the supernatant obtained after centrifugation at 800g for 10 min was stored in the carbon dioxide freezer until use. Normal or erythropoietin-containing rabbit serum<sup>1</sup> was used for both sensitization (beginning at 5–6 weeks of age) and shock; weekly doses of 0.5 ml. were administered through the subcutaneous route. Most instances of fatal anaphylaxis occurred after the third weekly dose; a few occurred after each of the next two doses, but none at an earlier time. Only mice that died of classical anaphylactic shock<sup>5</sup>, which generally occurred within 1 h after administration of the serum, were taken into account in the data to be presented.

There was no difference in allergic response to the normal or erythropoietin-containing rabbit serum, and so these data were combined and are presented in Table 1. It is apparent that a proportion of female mice which received a single dose of leukaemic spleen extract at 2 days of age were protected from fatal anaphylaxis. These mice were not detectably leukaemic at this time. The difference in incidence of fatal anaphylaxis, from the point of view of sex, in mice which have not been inoculated with leukaemic spleen extract was notable.

The response of females to inoculation of spleen extract containing both *Eperythrozoon coccoides*, a splenomegalogenic agent<sup>6</sup>, and the lactic dehydrogenase-elevating (LDH) virus indicated that the leukaemic spleen extract was specifically responsible for inducing resistance to fatal anaphylaxis.

The leukaemic agent consistently induces neoplasia (in an average of 75 per cent of infected mice) in about 100 days if the mice are infected within a few days of birth. The incidence of the disease is rapidly reduced if mice are infected at a later age<sup>2</sup>. It was interesting to determine whether the capability of a virus-containing extract to induce anaphylactic tolerance was correlated with its capability to induce neoplasia. The results are given in Table 2. The data suggest such a relationship, because the incidence of fatal anaphylactic shock increased when mice were infected at later ages.

Anaphylaxis is a complex phenomenon, consisting of an immunological phase followed by a series of events which may terminate in death, the end point used in these experiments. Whether the leukaemic extracts affect the initial immunological response or a later stage remains to be determined. An increasing body of evidence indicates that infection of mice with several different leukaemogenic viruses remarkably depresses production

Table 1. RESISTANCE OF MICE INOCULATED WITH LEUKAEMIC SPLEEN EXTRACT TO FATAL ANAPHYLACTIC SHOCK

Preliminary treatment of mice*	Sex	No. died/ No. sensitized†	Per cent
None	Male	0/41	0
None	Female	16/57	28
Virus-induced leukaemic spleen extract	Male	0/59	0
	Female	0/117	0
Series I transplanted leukaemic spleen extract‡	Female	2/64	3
Spleen extract containing <i>E. coccoides</i> and LDH virus	Female	7/30	23

\* In all examples the treatment consisted of a single inoculation of a 10 per cent extract, 0.05 ml. given subcutaneously and intraperitoneally at 2 days old.

† With rabbit serum beginning at weaning. See text for regimen used.

‡ A transplantable tumour originally virus-induced<sup>2</sup> and now in its 110th transplant generation.

Table 2. INDUCTION OF ANAPHYLACTIC TOLERANCE AS A FUNCTION OF AGE OF INOCULATION WITH A LEUKAEMIC EXTRACT

Age of mice at inoculation* (days)	No. died/ No. sensitized†	Per cent
2	0/15	0
21	3/28	11
42	7/25	28

\* Females were inoculated with a virus-induced leukaemic spleen extract.

† The mice were sensitized 5–6 weeks after infection in all cases.

of antibody to exogenous antigens administered subsequent to infection<sup>7-11</sup>. It is possible, therefore, that the induction of anaphylactic tolerance is the result of an abnormality at the immunological level rather than at a later stage in the anaphylactic reaction.

If the leukaemia virus was responsible for the induction of anaphylactic tolerance, it was surprising that the extract from the transplantable tumour was also effective (Table 1). This particular tumour arose from a virus-induced case in 1962 (ref. 2) and is now in its 110th transplant generation. Attempts to demonstrate the presence of the leukaemia-inducing virus in this type of material by ordinary means as early as in the third and fifth transplant generations have failed. In only one case was virus demonstrated: before the transplantation of the nineteenth generation, recipient mice were treated for several weeks with cortisone. An extract of a resulting neoplastic spleen induced two cases of leukaemia with a very long latency. It can be concluded, therefore, that virus is still present in this transplantable leukaemia. Its considerable activity in inducing anaphylactic tolerance suggests that the tolerance-inducing agent in the transplantable tumour could be an attenuated (non-oncogenic) form of the leukaemic agent. Such a possibility was also considered in the case of a culture of the Friend agent which was also extremely low in oncogenicity but active in inducing resistance to infection of mice with potent Friend virus<sup>12</sup>. It is possible that inhibition of fatal anaphylaxis or depression of antibody to exogenous antigens may be found useful to detect potential leukaemogenic viruses whether or not they are actually oncogenic in the test host.

## CYTOLOGY

### DNA Content of Monotremes

INTEREST has recently been focused on the DNA content of the different classes of vertebrates. Although the number and size of chromosomes in placental mammals vary considerably, biochemical determinations have shown that the DNA content is relatively constant<sup>1</sup>. Atkin *et al.*<sup>2</sup>, using the microdensitometer method, found that the placental mammals constitute a fairly uniform group with regard to the total genetic content, as do birds

which have a DNA content about half (44-59 per cent) that of eutherians. Reptiles, however, fall into two distinct categories<sup>3</sup>: the order *Squamata* has a DNA value 60-67 per cent that of placental mammals, while *Crocodylia* and *Chelonina* have 80-89 per cent. These percentages agree with those obtained by Ohno<sup>3</sup>, who measured chromosomal areas of colchicized metaphases.

The difference between the DNA content of the placental mammals and birds suggests that these two classes of warm-blooded vertebrates have evolved from different lineages. It would be interesting to know where the other two groups of mammals, the marsupials and monotremes, belong. No information is available for the monotremes, but Ohno<sup>4</sup> found by estimation of the chromosomal area that the American opossum (*Didelphis virginiana*) has a value of 94 per cent of that of placental mammals.

Using the biochemical method of Schmidt and Thannhauser<sup>5</sup>, we measured the DNA content of two monotremes, the platypus (*Ornithorhynchus anatinus*) and the echidna or spiny ant-eater (*Tachyglossus aculeatus*); the marsupial, potoroo (*Potorous tridactylus*); and the rat (*Rattus norvegicus*) as a representative of placental mammals (Table 1). The values agree well with an assay of the DNA content by the method of Schneider<sup>6</sup> which we used for comparison.

Table 1. DNA CONTENT EXPRESSED IN MG/100 G OF FRESH HEART TISSUE

	$\bar{x} \pm S\bar{x}$	Relative content (per cent)
♂ Rat	29.9 ± 0.24	100
♂ Potoroo	24.2 ± 0.20	81.0
♂ Echidna	27.9 ± 0.18	93.3
♀ Platypus	29.5 ± 0.27	98.6

The higher DNA value for the female platypus compared with the male echidna probably results from the presence of the extra sex chromosome. Each value given in Table 1 is the mean of four separate estimations, using a Unicam spectrophotometer for the ultra-violet readings and the same standards and chemicals throughout the experiments. Heart tissue was adjudged the most suitable for the purpose because the heart is one of the organs least likely to be affected by variations in the condition of the animal, and the ratio of the nucleus to the cytoplasm remains fairly constant even for animals in poor condition; moreover, heart tissue does not present the problem of polyploidy as does the liver. In the case of the rat, two hearts were used for each determination in order to minimize the difference in weight. The heart tissue was kept at -10° to -15° C for 24 h, which facilitated the subsequent homogenization.

The results show that the DNA content of the potoroo is about 10 per cent lower than that of the American opossum, apparently the only other marsupial which has been examined<sup>4</sup>. The difference may be associated with the fact that the potoroo has only about half the number of chromosomes (12 in female; 13 in male) of the opossum (2n=22), and one may compare it with the 10 per cent difference in DNA value between the creeping vole (*Microtus oregoni*, 2n=17-18) and other placental mammals<sup>2</sup>. Atkin *et al.* have suggested that the low number of chromosomes in the vole is associated with the loss of a number of centromeres with their adjacent heterochromatic chromosomal material<sup>2</sup>. In the case of the potoroo, Sharman and Barber<sup>7</sup> have shown that autosomal material has been incorporated in the sex system of the animal.

The monotremes have been compared with the reptiles because of certain anatomical and physiological similarities in these two groups of vertebrates<sup>8,9</sup>. The chromosome complements of the monotremes have been described as resembling those of snakes and birds because of the presence of macro-elements and micro-elements<sup>10</sup>. Our work on the chromosome numbers of the monotremes<sup>11,12</sup>, however, has shown that their karyotype can be regarded as an extreme mammalian type rather than having close affinity with those of *Aves* and *Ophidia*.

In a preliminary survey of the genetic content of the three groups of mammals using the technique of Ohno<sup>3</sup>, we have found, by comparing chromosomal areas of leucocytes in tissue culture, a value of 92.1 per cent for the echidna compared with that of man. This is in good agreement with our biochemical estimations of the DNA content which gave a value of 93.3 per cent for the echidna compared with that of the rat.

Thus in this respect also the monotremes seem to show a closer affinity to other mammals than to birds or reptiles.

We thank Dr R. K. Crowden for his advice and help with the biochemical techniques.

### Mitogenic Effect of Phytohaemagglutinin at Different Ages

WHILE investigating the effect of myelotoxic drugs on the mitotic potential of phytohaemagglutinin-stimulated lymphocytes from peripheral blood, we found that the mitotic index (number of mitoses/1,000 cells) and percentage blast transformation was frequently lower in elderly individuals than in younger subjects. This report presents the results of standardized investigations of cell cultures, from 293 apparently healthy individuals ranging in age from 1 to 98 years after stimulation with phytohaemagglutinin. To avoid circadian influences all work was carried out at the same time of day, beginning with venipuncture at 9.00 a.m. To test the reproducibility of the method, duplicate cultures were made from the same individuals at the same time. The mean difference in mitotic index in duplicate cultures from ten subjects was  $0.9 \pm 4.4$  (standard deviation). The mean difference in blast transformation of duplicate cultures was  $5.1 \pm 5.5$  per cent. In seven subjects, ages 21–30 yr, cultures were repeated eight to thirty-five separate times during several weeks. The coefficient of variation ( $S.D./X$ ) for mitotic index (Fig. 1) in any given subject ranged from 25 per cent to 40 per cent. The value of mean  $\pm 1$  S.D. for mitotic index was the same for each individual so tested in this age group.

Fig. 1. Variations in mitotic index.

Fig. 2 shows the mitotic index of cultures stimulated with phytohaemagglutinin as a function of age of the cell donor. Analysis of these data yielded a linear regression coefficient ( $r$ ) of  $-0.330$ . With a sample of 289 and a value of  $r$  greater than 118, a significant correlation was found at the 95 per cent level of confidence. The values obtained for children of less than 12 yr old deviated somewhat from the regression curve. Prepubertal children showed a mitotic index considerably smaller than that which developed at adolescence, so that a pubertal peak in the mitotic index was observed. Regression analysis for the mitotic index versus age from age 13 on revealed a value for  $r$  of  $-0.427$ , which confirms an increase in slope when the first decade is eliminated. This correlation coefficient was also significant at the 95 per cent level. The critical value for  $r$  was 0.126 with a sample size of 254.

Fig. 2. Mitotic index versus age.

Blast transformation (mitoses + blasts) also varied universally with age (Fig. 3). The regression coefficient which represents the entire sample was  $-0.273$ , significant at the 95 per cent level with a critical value of 0.117 and a sample of 293, while that for age 13 and older showed a value for  $r$  of  $-0.485$ , also significant at the 95 per cent level with a critical value of 0.125 and a sample of 259. Data on ages 1–12 showed a positive value, but the sample analysed was too small to be significant.

The coefficient of determination showed that 23.5 per cent of the variation in blast transformation was accounted for by age, from age 13 onwards. This is significantly different from zero at the 95 per cent level of confidence. Sex and race did not play a significant part in these variations throughout our work.

The mean and standard deviation of mitotic index and blast transformation was compared in all subjects between 21 and 30 yr and between 71 and 80 yr of age (Table 1). A significant statistical difference was found between these age groups ( $P < 0.001$ ).

Interchange of plasma from old and young individuals demonstrated that the chief factor in diminishing mitotic potential with age is a function of the cell rather than the plasma.

Limited proliferative function of lymphocytes may be the result of acquired errors in cell division. Jacobs

Fig. 3. Blast transformation versus age. —, Mitosis plus blasts for all ages was  $678.335 + (-3.022)$ ; ···, mitosis plus blasts, ages 1–12 yr, was  $44.045 + 73.012$ ; ---, mitosis plus blasts, aged 13 yr onwards, was  $690.324 + (-3.240)$ .

*et al.*<sup>1,2</sup> have shown increasing aneuploidy in leucocyte cultures of ageing humans. In some cases this is associated with a loss of one chromosome from the 6–12-X series<sup>3</sup>. The large frequency of mitotic non-disjunction in germ cells of older women is well known, but definitive data to explain the refractoriness of lymphocytes from older people to phytohaemagglutinin are not yet available.

## Hepatic Response to Lysosomal Effects of Hypoxia, Neutral Red and Chloroquine

THE histochemical detection of early changes in the characteristics, distribution and enzyme contents of lysosomes, as well as their cycles of appearance and disappearance, affords a sensitive index of toxic effects on the cell. Hypoxia is known to labilize lysosomes<sup>1</sup> and might be expected to render them more susceptible to adverse influences. Selective uptake of neutral red by lysosomes<sup>2,3</sup> and the stabilization brought about by chloroquine<sup>4</sup> constitute further experimental manipulations to which lysosomes can be subjected. We have made detailed observations of lysosomal behaviour in these conditions as a preliminary to the study of lysosomal changes in the damaged liver of the rat.

Individual male rats (Carworth Farm E strain, 130–150 g, 5–6 weeks old) were sealed in 1 gal jars for 60 min. Animals (three in each group) were killed at 0, 1, 3, 6, 9, 12, 18 and 24 h after removal from the jars. One rat in each group had been given 125 mg/kg chloroquine daily for 12 days by tube; a second rat was injected intraperitoneally with neutral red (400 mg/kg) immediately following hypoxia; the third underwent no further treatment. Comparisons were made with similar rats not subjected to hypoxia. Liver slices were fixed in formol sucrose (acid phosphatase) or formol chloral hydrate ( $\beta$ -glucuronidase) for 18–24 h and transferred to hypertonic gum sucrose (18–24 h). Sections 8  $\mu$  thick were cut on a freezing microtome. Acid phosphatase was demonstrated by the techniques of Gomori<sup>5</sup> (used shortly after incubating  $\beta$ -glycerophosphate medium for 1 h at 37° C and filtering<sup>6</sup>) and Barka and Anderson<sup>6</sup>. For  $\beta$ -glucuronidase the methods of Hayashi *et al.*<sup>7</sup> and Fishman and Goldman<sup>8</sup> were used. Some of the liver slices were also fixed in neutral buffered formalin and Lillie acetic acid alcohol (18–24 h), embedded in paraffin and then stained with haematoxylin and eosin and Feulgen nuclear stain, respectively.

The results are summarized in Table 1. Hypoxia has two striking effects: an initial general increase in hepatic lysosomes and in the intensity of enzyme-staining reactions (Fig. 1), followed later by labilization of lysosomal membranes as manifested by loss of particulate enzyme activity, appearance of diffuse activity and residual perinuclear distribution (Fig. 2). This increase in lysosomes and their subsequent labilization profoundly disturbs the integrity of the cells. The release of hydrolytic enzymes into the cell cytoplasm results in cell damage, reflected in intracellular oedema seen at 3–12 h following hypoxia. The nuclei are also affected by the lysosomal disturbance; many of them enter into prophase and cell division follows.

Fig. 1. Liver of rat subjected to hypoxia for 1 h and killed 3 h later. Section of fixed tissue stained for acid phosphatase by Gomori technique, showing the variety of lysosomes ( $\times 1,000$ ).

Fig. 2. A section similar to that shown in Fig. 1, but taken from a rat killed 6 h after hypoxia. Particulate enzyme activity is reduced, remaining principally in the perinuclear region; some diffuse cytoplasmic activity is present ( $\times 1,000$ ).

Fig. 3. Almost total loss of acid phosphatase in a rat subjected to hypoxia as before, treated with neutral red, and killed after 3 h ( $\times 1,000$ ).

Neutral red introduced after hypoxia brings about a great reduction in lysosomes, followed by an almost total loss of enzyme demonstrable histochemically in liver cells (Fig. 3). In comparison with the effects of hypoxia alone, this premature and abrupt release of hydrolytic enzymes into the cytoplasm causes more extensive damage to cells. Many more are swollen, and in addition most are vacuolated (Fig. 5). Moreover, abnormal mitotic figures are a feature at this stage, with cell division taking place earlier. The process of cell recovery is associated with an altered pattern of lysosomal enzymes. Acid phosphatase activity appears first in the periportal areas in sites from which neutral red has disappeared, while  $\beta$ -glucuronidase is seen in centrilobular lysosomes in which neutral red is still present. In time the normal pattern of enzyme activity is restored.

The morphology of liver lysosomes is altered in rats treated with chloroquine. The organelles are enlarged and aggregated together but remain in their normal sites.

Their membranes stain much more intensely than the inner matrix. By 6–9 h after hypoxia a greater intensity of staining reaction is visible. Over the interval 12–18 h, in addition to the existing enlarged lysosomes, fresh enzyme sites appear much smaller in size, more homogeneously stained and probably representing a new generation of lysosomes (Fig. 4). The cytoplasmic vacuoles seen in sections stained with haematoxylin and eosin seem to correspond with enlarged lysosomes. Feulgen preparations reveal no signs of cell division, except at 12 h after hypoxia where a few nuclei are seen in prophase and even fewer in any other stage of mitosis.

Besides the suggested responsibility of lysosomal enzymes for cellular alterations in damaged or autolysing

Fig. 4. Lysosomal effects of 12 day feeding of chloroquine followed by exposure to hypoxia in a rat killed 18 h after hypoxia. Large lysosomal aggregates are present, together with small foci of acid phosphatase activity, probably representing new lysosomes ( $\times 1,000$ ).

Fig. 5. Intracellular oedema and vacuolation in the liver of a rat subjected to hypoxia for 1 h, treated with neutral red, and killed 9 h later ( $\times 1,000$ ).

tissue<sup>9</sup>, a role in mitosis has been proposed more recently by Allison and Mallucci<sup>10</sup> and by Hirschhorn and Hirschhorn<sup>11</sup>. According to these authors, release of lysosomal enzymes in some way initiates cell division. Our results show that in rat liver hypoxia results in an increase in the number of lysosomes, apparently of a more labile character, the release of the enzymes of which seems to initiate cell division and also causes cell damage. The action of neutral red provokes a more rapid release of lysosomal enzymes and accelerates the process of cell division associated with abnormal mitosis and clumping of chromosomes. Evidence for abnormal mitosis and nuclear disorganization has been presented<sup>3,12</sup>. On the other hand, stabilizing the lysosomal membranes by means of chloroquine prevents the post-hypoxia nuclear changes.

The importance of the cycle of changes undergone by lysosomes in relation to hepatocellular morphology emerges from these studies. Superimposed on the background of minimal morphological alterations induced by hypoxia, the effect of neutral red is striking in terms of intracellular oedema and vacuolation. These manifestations closely correspond to the lysosomal changes. Chloroquine, on the other hand, preserves lysosomal integrity after hypoxia, without evidence of liver damage.

Our observations emphasize that effects on lysosomes are reflected in both cytoplasmic and nuclear changes. They offer the hope that a "provocative" test for hepatic susceptibility to damage may be evolved along these lines.

We thank the Nuffield Foundation for support, Margaret Morris and Jennifer Smith for technical assistance and D. Ellames for the photographs.

### Nuclear Bleb Formation in Human Bone Marrow Cells during Cytosine Arabinoside Therapy

ABNORMAL nuclear blebs have recently been reported in the bone marrow cells of patients undergoing 5-fluorouracil treatment for neoplastic disease<sup>1</sup>. Ultrastructural examination of these blebs revealed that they enclose areas of cytoplasmic material within their bulging projection and are unlike the nuclear invaginations described in some malignant cells<sup>2</sup> or the projections of nuclear material reported in certain chromosome abnormalities<sup>3</sup>. Investigation in our laboratory of the bone marrow of patients undergoing treatment with cytosine arabinoside revealed identical nuclear blebs containing cytoplasmic material in immature granulocytes. The condition was first noted in bone marrow samples 45 h after a single intravenous administration of the agent, 1,200 and 1,500 mg/m<sup>2</sup> body surface.

The bleb formations were frequently found to contain a varied assortment of cytoplasmic organelles (Fig. 1). Characteristically they occur as oval or round protrusions on the outer periphery of the nucleus. A thin sheet of nucleoplasm, with the exterior nuclear membrane intact, appears to be thrown out in loop-like fashion from the nuclear surface. The cytoplasmic material enclosed within the bleb is, in turn, segregated from the nucleus by double membranes (Fig. 2).

In some of these segregated areas of cytoplasm distinct cytoplasmic organelles were not observed in the sections examined (Fig. 3). The presence in these blebs of particulate matter of greater density than in the surrounding cytoplasm suggests that the blebs are isolated, and that hydrolytic activity might possibly be present within the isolated inclusions.

Fig. 1.

Fig. 2.

Fig. 3.

It is of particular interest to note that this nuclear abnormality, induced by two similarly acting chemotherapeutic agents, resembles the projections of the nuclear envelope which were recently demonstrated to be a naturally occurring attribute of the Burkitt lymphoma cells<sup>4</sup>.

More detailed studies are at present under way in an attempt to elucidate the mode of formation of this phenomenon as well as its functional significance in the cell.

## PHYSIOLOGY

### Predominantly Electrochemical Nature of Biological Power-producing Reactions

THE food taken in by a human being on a normal diet is equivalent, if all is converted to heat, to about  $3 \times 10^6$  cal/24 h. If this energy was spent at a constant rate, with 100 per cent efficiency of conversion to mechanical work, the power provided would correspond to about 160 W.

For calculating the actual power available to the human organism there are, in principle, only two ways of converting the energy of chemical reactions to mechanical work. The first of these is that of the heat engine, and

the efficiency for this conversion is given by the well known Carnot cycle fraction

$$\frac{T_{\text{high}} - T_{\text{low}}}{T_{\text{high}}}$$

where the  $T$ s are, in °K, the high and low points of the temperature of the "working fluid". For a human organism at room temperature, this fraction has a value of about 1/60, so that if the principle of the heat engine is assumed in estimating the fraction of the energy conversion of the chemical reaction between food and oxygen to water and carbon dioxide available to power a human organism, the (average) power would correspond to  $160 \times 1/60 \approx 2.5$  W.

This value is much less than that which the human organism is able to make available to itself, because the circulatory system alone operates under a roughly constant power of about 10 W.

It seems, therefore, that at least a substantial part of the energy conversion of the human organism must take place by the (less well known) principle of the electrochemical conversion of the energy of chemical reactions to work, in which the Carnot efficiency expression does not limit the degree of this conversion ("cold combustion").

This simply made conclusion seems to have a broad significance. Thus it has often been stated that electron transfer reactions play a part in certain biological processes. It has not yet been accepted that only the electrochemical path of conversion of the energy of chemical reactions to mechanical work is consistent with the observed efficiency in the use of chemical energy in the body. This is possibly because of the lack of availability in English of books on more recently discussed electrokinetic principles.

In the normal concept of the electrochemical engine, an electric motor receives energy after electrochemical interfacial reactions in a fuel cell have occurred, and is assumed to convert this to mechanical work at nearly 100 per cent efficiency. The existence of an analogue of this conversion of electric energy to mechanical power is indicated in the electrical activity of muscle function.

Thus the present work supports electrochemical reaction mechanisms as those by which biological cells feed on organic materials and oxygen. A model of biological cell action which is similar to that of an electrochemical fuel cell was formulated by Del Duca and Fuscoe<sup>1</sup>.

It is noteworthy that if a biological organism converts the energy of the reaction between organic compounds and oxygen to available mechanical energy by an electrochemical mechanism, heat may be evolved or absorbed in the reaction. If the entropy of the overall reaction ( $\Delta S$ ) is sufficiently positive, a net cooling effect during production of energy by the organism could occur (and would so occur if the sum of the overpotentials associated with the hypothetical electrochemical processes of the biological cell were less than  $T\Delta S$ ). An organism could conceivably then extract some electrical energy from the heat energy of its surroundings.

## Effect of a Branching Capillary Network on the Differential Flow Velocities of Plasma and Corpuscles

MEASUREMENT of the relative velocities of corpuscles and plasma by timing the travel of traceable materials between different points in the living body<sup>1,2</sup> shows that the mean transit time of the cells is appreciably less than that of the plasma and this is generally attributed to the effect of axial drift of the red cells in the minute vessels. Groom, Morris and Rowlands<sup>3</sup> showed that the whole of the cell arrival curve was displaced in time ahead of the plasma arrival curve. Thus some of the red cells apparently advanced bodily ahead of the plasma with which they were injected. Whitmore<sup>4</sup> compared these results with those of a theoretical hydrodynamic model, which he developed, and concluded that axial accumulation of cells in streamline flow should only affect the shape of the later portion of the cell-concentration curve; the initial rise of both curves should occur at the same moment and at a comparable rate. Thus such a model did not account for the observed time displacement of the whole cell curve ahead of the plasma curve and the advancement of the leading cells ahead of the plasma with which they were injected.

Whitmore further analysed the effect of pulsatile flow and flow deformation of the red cells and concluded that these could not account for the observed effect either. He suggested that the discrepancy could be explained by postulating a mode of flow in which the cells are constrained within an axial core, but move about freely within this core while the plasma moves freely and randomly between the core and all, or a portion, of the plasmatic layer. There is some support for Whitmore's theory of random movement in the observations of Bloch<sup>5</sup>, but I wish to direct attention to regular plasma and cell movements between the axial core and the peripheral zone which must occur in a capillary network at the sites of bifurcation because of displacement of cells by the partition wall of the branch.

Fig. 1 illustrates the effect of axial drift of red cells in blood flowing through a capillary network. The lines show approximate paths of red cells and the proximity of the lines represents the cell concentration. In region A there is axial accumulation of the cells such as develops in vessels of diameter less than about 250 $\mu$ . The diagram shows a progressive increase in cell concentration from the wall to the axis in conformity with the results of our experiments using slit-like glass channels<sup>6,7</sup>. At the bifurcation the stream is split through the central core so that in region B there is at first a concentration of cells near the inner wall of each branch. As the blood moves along each branch the cells migrate towards the axis and, if the branch is long enough, form an axial accumulation as indicated in region C. Immediately distal to the confluence the distribution of cells approximates to that shown in region D with a central core, with few cells,

Fig. 1.

separating the cell-rich axial streams coming from each branch. Again, in region E, given sufficient length of narrow bore vessel, the cells will drift axially to re-form a central accumulation. For simplicity only one division and one confluence are shown and the cell paths are illustrated in one plane only, but in an actual network there are many successive divisions at the arteriolar end, and many confluences at the venular end. The planes of branches in general vary successively so that the effects illustrated occur repeatedly and in many planes.

If the progressive increase in cell concentration from wall to axis does not obtain *in vivo*, significant transverse movements may not occur near confluences, but such movements must occur at sites of branching because, as Maude and Whitmore<sup>8</sup> have pointed out, a particle must be displaced radially if it enters a tube along a streamline which comes to lie at a distance from the wall less than the radius of the particle and this would apply near the dividing walls of a branch. Furthermore, it is well known from microscopic observation of the capillary circulation that there is a zone of plasma containing few or no cells near the wall of most small vessels.

Thus in a capillary network there will occur reciprocal transverse movements of cells and plasma across the stream, with progressive separation of cells and plasma which were originally associated. The movements will be greater if there is axial drift of the cells as well as simple displacement by dividing walls.

I thank Dr R. L. Whitmore for his advice.

## Role of Intraluminal Precipitation in Secretion of Small Intestinal Calcium and Phosphate in the Dog

IN previous investigations of small intestinal calcium metabolism<sup>1</sup> it has been assumed that calcium in the lumen of the small bowel is entirely in solution. We examined the hypothesis that calcium exists in more than one phase, and investigated (a) the calcium composition of endogenous intestinal secretions, and (b) the calcium and phosphate content in the lumen 30 min after a dilute calcium solution had been introduced into closed segments of small intestine. We prepared two adjacent jejunal and two adjacent ileal segments *in situ* in seventeen fasted, anaesthetized dogs; each segment was approximately 20 cm long and contained two arcades of mesenteric vessels. The jejunal segments commenced 15 cm distal to the ligament of Treitz and the ileal segments ended 10 cm proximal to the ileo-caecal junction. We prepared the segments individually by tying 5 mm plastic cannulae, fitted with plugs, into each end. They were thoroughly flushed with saline at 37° C, and when the effluent was clear were flushed with air. When all were prepared, the four segments were flushed as quickly as possible with 200 ml. of saline followed by air. In five dogs no solution was introduced, the "empty" segments were left *in situ* for 1 h and the endogenous secretion was collected by washing with 25 ml. of 5 per cent mannitol. In twelve dogs we immediately introduced 10 ml. of a solution containing 1 mg of calcium (as calcium chloride) and 100 mg of

inulin. After 30 min the luminal contents were collected by drainage and analysed for calcium (using an Eppendorf flame photometer), phosphate<sup>2</sup>, and inulin<sup>3</sup>. All samples contained a small proportion of precipitate, and they were centrifuged as soon as they were obtained and the supernatant was analysed immediately for calcium and phosphate. The remainder of the sample was acidified with 0.2 ml. of concentrated hydrochloric acid and the mixed sample was reanalysed immediately for calcium and phosphate. This latter result was corrected for volume effects (acid added and samples removed), and concentration was calculated for the original volume. The quantity of calcium secreted into "empty" segments was calculated directly from the concentration of calcium in the washings and the wash volumes. When the calcium solution was introduced it was necessary to correct sample volume, for recovery by drainage is incomplete. Inulin was virtually unabsorbed during a 30 min period. The ratio of initial to final inulin concentration multiplied by the initial volume therefore gives total sample volume. This corrected volume was used to calculate total calcium and phosphate content of the segments.

Table 1 shows that endogenous calcium entered "empty" segments and was not homogeneous: calcium was present both in solution in the supernatant (S) and in the form of an acid-soluble precipitate (difference between S and T). The insoluble form was dissolved at pH 1.

Table 2 shows that 30 min after the calcium solution was introduced, the intraluminal contents were also in two

phases. Both calcium and phosphate were present in the precipitate. The proportion of precipitated calcium was much lower than in the "empty" segments. Table 2 also shows phosphate content of the samples where exogenous calcium was introduced. Unlike the calcium, most of the phosphate was in the precipitated form. Thus the distribution of phosphate resembled more closely the distribution of calcium in those experiments where no exogenous calcium was added (Table 1). In these cases, intestinal pH had no apparent influence on precipitation, for it was as common in jejunal (mean pH 6.90) as ileal (mean pH 7.65) segments.

We did not identify the acid-soluble precipitate. The phosphate was present in both phases, and so these data suggest the calcium and phosphate were precipitated in combination, although they may have precipitated independently.

On acidification, bubbles of gas were evolved, which suggests that the precipitate was at least in part a calcium carbonate or bicarbonate complex. Calcium and phosphate precipitation within the lumen of the small intestine should be evaluated in investigations of endogenous and exogenous calcium and phosphate metabolism. It represents an appreciable fraction of endogenous calcium and phosphate secretion.

## Neurosecretory System of Heteroptera (Hemiptera) and Role of the Aorta as a Neurohaemal Organ

It is well known that the generalized pattern of the neurosecretory system of an insect consists of the medial and lateral groups of neurosecretory cells in the protocerebrum, the medial and lateral neurosecretory pathways and the corpora cardiaca<sup>1,2</sup>. The A- and B-materials elaborated by these groups of cells are transported along their respective pathways to be stored in the corpora cardiaca, from where they are released into the general blood circulation to fulfil specific physiological functions. In an insect, therefore, the corpora cardiaca are considered to form the storage-and-release (neurohaemal) organ for the two types of materials.

The neurosecretory systems of five species of Heteroptera, *Dysdercus koenigii* (Pyrrhocoridae), a species of *Graptostethus* (Lygaeidae), *Ranatra elongata*, *Nepa cinerea* (Nepidae) and *Belostoma indica* (Belostomatidae), examined with the aid of paraldehyde-fuchsin and Humberstone's performic acid-victoria blue (PAVB) *in situ* techniques<sup>3</sup> and routine histological methods<sup>4</sup>, shows an anatomical pattern which varies considerably from the basic pattern for the hexapods. In these insects, while

the neurosecretory cells and pathways are always positive to these tests, the corpora cardiaca do not stain at all.

There are two groups of between eight and ten A-cells, which stain deep purple with the paraldehyde-fuchsin and these are present in the pars intercerebralis medialis of the protocerebrum. With the PAVB histo- and cytochemical technique specific for cystine and/or cysteine an equal number of cells are stained greenish-blue in the same locus, suggesting that the cystine rich neurosecretory material is elaborated by the A-cells (Fig. 1, and *ns c* in Fig. 2). Humberstone's PAVB technique<sup>3</sup> is a modification of Adams and Sloper's performic acid-alcian blue technique<sup>5</sup> for the histochemical demonstration of cystine and/or cysteine and, therefore, like its predecessor this technique is also specific for cystine and cysteine. The axons of the cells of each group converge to form the neurosecretory pathway (*ns p* in Fig. 2). The two pathways after crossing each other in the upper equatorial half of the protocerebrum run along its anterior and ventral surfaces, then along the deuto- and trito-cerebrum and emerge from the tritocerebrum as the nervi corporis cardiaci I (NCC I, Fig. 2). It is worth mentioning here that the emergence of the NCC I from the tritocerebrum is unique to these hemipteran species, which is not so in the case of the basic pattern where the NCC I emerge from the protocerebrum<sup>1,2</sup>. The NCC I after running for some distance between the aorta and the alimentary canal become attached superficially to either the ventral or to the dorsal surface of the corpora cardiaca (*c c*,

Fig. 1. Dissected protocerebral parts of the bug, *D. koenigii*, showing two groups of nine A-cells of the pars intercerebralis medialis. (Paraldehyde-fuchsin *in situ*,  $\times c. 114$ .)

Fig. 2. Neurosecretory system of *R. elongata*, mounted with dorsal surface facing upwards, showing the median neurosecretory cells, their pathways, the NCC I by-passing the corpora cardiaca and entering the aorta wall, and the NCC II (clearly visible on the right) entering the corpus cardiacum apically. The corpora allata have been removed. (PAVB, *in situ*,  $\times c. 50$ .)

Fig. 3. Cross-section ( $7\mu$ ) of a PAVB bulk-stained preparation of *R. elongata*, showing cystine-rich neurosecretory material in the aorta wall. ( $\times c. 135$ .)

Fig. 4. Cross-section ( $12\mu$ ) of a series of the bug, *D. koenigii*, routinely stained with paraldehyde-fuchsin showing A-cells and B-cells in the protocerebrum. ( $\times c. 114$ .)

Fig. 5. Magnification of the postcerebral endocrine organs of *R. elongata*, showing fanning out of the fibres of NCC I (arrow) before they enter the ventral wall of the aorta. The sheath (*sh*) of the NCC I is quite distinct from the corpora cardiaca. Absence of the material in the corpora cardiaca is as noticeable as in the corpora allata. (PAVB, *in situ*,  $\times c. 81$ .)

Figs. 2 and 5) and after passing along the surface of the glands enter the aorta wall ventrally or laterally. The corpora cardiaca and the NCC I are easily separated without damaging either structure; there seems to be no connexion between them and even the neurilemma covering them are separate (*sh*, Fig. 5). Before they penetrate the aorta wall the fibres of the NCC I fan out considerably (arrow, Fig. 5) and run for about half the length of the aorta where they gradually disappear. There is always abundant neurosecretory material in the aorta wall, as in the corpora cardiaca of orthopteroid insects, but it is not present in the lumen of the aorta, as reported by Herlant-Meewis and Paquet<sup>6</sup>. The material is distributed uniformly among the entire circumference of the aorta wall (Fig. 3). The bulk-stained preparations (circled in Fig. 5) and the sections (circled in Fig. 3) suggest that the material is localized within the axons. This contrasts with the corpora cardiaca of the Orthopteroid species where the material is stored in the intercellular spaces, and it is an interesting feature revealed by this work. It is possible, therefore, that the aorta wall acts as the storage organ for the neurosecretory material made by the A-cells. From the aorta wall it is probably released into the general blood circulatory system for specific physiological purposes. Thus the aorta wall appears to be the neurohaemal organ for the A-material.

Between four and six B-cells, stained with the light green of the counterstain of the paraldehyde-fuchsin technique, are present in the pars intercerebralis lateralis of each protocerebral lobe (Fig. 4). B-cells, being negative to PAVB, can be said to be devoid of cystine. The axons of these cells converge to form lateral neurosecretory pathways which, after passing through the proto- and deuto-cerebrum of its side emerge from the tritocerebrum just outside the NCC I, as the NCC II. Distally, the NCC II join the corpora cardiaca (NCC II, Figs. 2 and 5). In this way the neurosecretory material elaborated by the B-cells, transported by the lateral neurosecretory pathways and the NCC II, is stored in the corpora cardiaca from where it is probably also released. For B-material therefore the corpora cardiaca serve as neurohaemal organs.

We have shown clearly that there may be two neurohaemal organs in some insects, that is, the aorta wall which is responsible for the storage and release of A-material and the corpus cardiacum for the B-material.

The presence of material in the aorta wall of heteropteroid insects, at the level of the corpora cardiaca, has been noted several times<sup>7-9</sup>, but its presence has been interpreted in different ways. According to Nayar<sup>7</sup> and Ewen<sup>8</sup>, in *Iphita limbata* (Pyrrhocoridae) and *Adelphocoris lineolatus* (Miridae) the corpora cardiaca are the storage organs, like the neurohaemal organ of the Orthopteroid insects<sup>2,11</sup>, but these authors interpreted the presence of A-material in the aorta wall as a result of the release of the neurosecretory material from the storage organ. Johansson<sup>9</sup> has also observed material in the aorta wall of *Oncopeltus fasciatus* (Lygaeidae) but has not identified the exact pathways to the aorta wall. *Rhodnius prolixus* (Reduviidae) is perhaps the only hemipteran so far investigated for which it has been categorically mentioned that the axons of the NCC I end in the corpora cardiaca with no information about the presence of neurosecretory material in the aorta wall<sup>10</sup>.

There is evidence of intrinsic secretion of A-material in the corpora cardiaca<sup>11,12</sup>. If this is so, then the presence of the material in this organ observed by Nayar<sup>7</sup> and Ewen<sup>8</sup> could possibly be explained as secretion in the glands and not the stored material elaborated by the A-cells. The failure of such an intrinsic secretion in the present work could be because the insects were not in a physiological state for such a secretion. For the same reason Johansson<sup>9</sup> may have failed to observe the material in the corpora cardiaca. The above discussion, however,

suggests that the aorta wall, but possibly not the corpora cardiaca, is the storage and release organ for A-material in Hemiptera.

### Effect of Saxitoxin on the End Plate of Frog Muscle

TETRODOTOXIN and saxitoxin are neurotoxins with very similar biological actions, though they are chemically distinct. Tetrodotoxin reduces the amplitude of the end plate potential elicited by neural stimulation. At the same time, however, the end plate membrane remains entirely responsive to acetylcholine<sup>1-3</sup>. Kao and Nishiyama<sup>4</sup> found that the actions of saxitoxin on the neuromuscular system are similar to those of tetrodotoxin. The blockade of neuromuscular transmission by saxitoxin affects the motor axon and muscle membrane, while the end plate receptor is not affected.

In order to confirm our previous results, the action of both toxins on the end plate potential and the iontophoretically elicited acetylcholine (Ach) potential was studied in this experiment. Isolated sciatic nerve-sartorius preparations of frog were used in all these experiments.

Fig. 1 shows typical records of alternate end plate and Ach potentials both before and after the application of saxitoxin and tetrodotoxin. Both toxins always reduced the amplitude of the end plate potential after a time, but

Fig. 1. End plate and Ach potentials before and after application of 0.01 µg/ml saxitoxin (A) and of 0.1 µg/ml tetrodotoxin (B). Upper traces: alternate end plate potentials and Ach potentials. Upward deflexions in lower traces: strength of current through the Ach pipette. The concentration of curare was  $2.5 \times 10^{-4}$  g/ml. in A and  $2.0 \times 10^{-4}$  g/ml. in B. 3-6 mmolar calcium in saline solution was present in both. In A: a is the control; b, 20 sec after perfusion with solution containing saxitoxin; c, 140 sec; d, 260 sec after perfusion with normal saline solution. In B: a is the control; b, 80 sec; c, 210 sec after perfusion with solution containing tetrodotoxin.

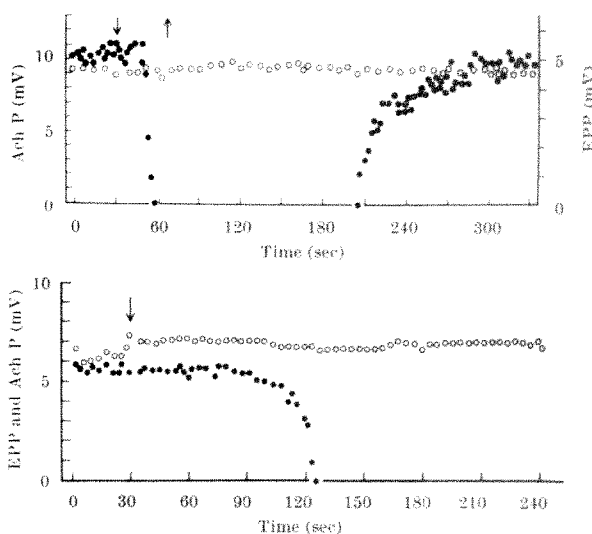

Fig. 2. Time course of the effect of 0.01 µg/ml saxitoxin (upper graph) and 0.1 µg/ml tetrodotoxin (lower graph). The same experiments as in Fig. 1. ●, End plate potentials (EPP); ○, Ach potentials. At arrows the toxins were applied, and at the inverted arrow the toxin was washed out.

Fig. 3. Alternate records of end plate potentials and catelectrotonic potentials on the neuromuscular junction before and after application of 1.0 µg/ml saxitoxin. a, Control; b, 25 min after application of the toxin. The preparation was previously treated with  $2.5 \times 10^{-4}$  g/ml curare. The current for constant rectangular pulses across the muscle membrane was monitored in the lower traces.

they had no effect on the amplitude of the Ach potential. An almost complete block of neuromuscular transmission occurred less than 30 sec after the first sign of reduction in the end plate potential with both toxins, but even in such a completely blocked state, the amplitude of the Ach potential was not affected. The time course of the effect of both toxins is shown in Fig. 2.

The effects of both toxins on the passive electrical properties of the muscle membrane in the region of the end plate were also examined. A rectangular outward current of constant intensity was applied through a second intracellular microelectrode and both end plate and catelectrotonic potentials were recorded alternately (Fig. 3). Even when a high concentration of saxitoxin, sufficient to block the neuromuscular transmission completely, was applied, the electrical properties of the end plate region remained unchanged. Saxitoxin, therefore, does not alter the effective membrane resistance. A similar effect of saxitoxin on the crayfish neuromuscular junction was recently reported<sup>5</sup>.

This experiment shows the similarity between the actions of saxitoxin and tetrodotoxin on the frog neuromuscular junction. Both toxins block the generation of spike potentials in nerve and muscle fibres by interfering selectively with the initial increase in sodium permeability, but they do not affect the end plate receptor. This finding is a welcome addition to the evidence showing that conduction in nerve and muscle membrane is fundamentally different from transmission across synapses. This evidence was recently reviewed by Kao<sup>6</sup>. Kao and Nishiyama<sup>4</sup>, however, found discrepancies between the actions of saxitoxin and tetrodotoxin on the miniature end plate potentials. In some cases, saxitoxin produced a transient increase in the frequency of these miniature end plate potentials and the amplitude of these potentials

became somewhat smaller after a long period of immersion. This problem awaits further experiment.

I thank Dr E. J. Shantz of the US Army Chemical Corps for providing the saxitoxin and Sankyo Co., Tokyo, Japan, for providing the tetrodotoxin.

### Effect of $\alpha$ -Methyl Dopa on Acetylcholine Content of Rat Brain, Heart and Intestine

RESERPINE, guanethidine and syrosingopine, which are potent hypotensive drugs, have been shown to produce side effects suggestive of increased parasympathetic activity. Some of these effects, such as bradycardia and diarrhoea, are attributable to an increased acetylcholine content of heart and intestine<sup>1,2</sup>.

$\alpha$ -Methyl dopa, a potent inhibitor of dopa-decarboxylase, is a widely used hypotensive drug of clinical value. Its hypotensive action is believed to be caused by the inhibition of dopa-decarboxylase and subsequent depletion of the catecholamines and 5-hydroxytryptamine of the tissues. Nevertheless, recent studies suggest that this effect is not the result of decarboxylase inhibition<sup>3,4</sup> but probably results from an action more like that of reserpine and guanethidine. Like reserpine and guanethidine,  $\alpha$ -methyl dopa produces symptoms such as postural hypotension, bradycardia and diarrhoea<sup>5</sup>. It has already been shown that reserpine, which causes a depletion of 5-hydroxytryptamine and catecholamines, increases the acetylcholine content of central and peripheral nervous tissues, while its side effects are caused by an increase of acetylcholine content<sup>6</sup>. It was therefore considered worth while to study the effect of  $\alpha$ -methyl dopa on the acetylcholine content of brain, heart and intestines.

A group of eight male albino rats (weighing 100–150 g) were injected twice daily with  $\alpha$ -methyl dopa (100 mg/kg) intramuscularly for three days. An equivalent amount of normal saline was injected in a similar group of six control rats. The animals were killed on the third day, 2 h after the last injection. Extracts of brain, heart and a piece of intestine were prepared by using buffered saline (pH 4.0) and eserinated Ringer solution after the method of Richter and Crossland<sup>7</sup>. The tissues were not frozen beforehand but were placed in a cooled extractant solution to avoid reducing the yield of acetylcholine by freezing. The extractant solution was cooled by immersion in an ice salt mixture. The acetylcholine content was assayed on frog rectus muscle bathed in eserinated (10<sup>-6</sup>) Ringer solution.

The results (Table 1) show that  $\alpha$ -methyl dopa causes an increase in the acetylcholine content of brain, heart and intestine.

The increase in acetylcholine content of heart and intestine may account for the side effects of  $\alpha$ -methyl dopa such as bradycardia and diarrhoea.  $\alpha$ -Methyl dopa is reported to produce sedation when used in hypertension in human subjects<sup>8,9</sup> and in animals<sup>10</sup>. The sedation may be responsible for an increase in the total brain acetyl-

choline because it has been shown that the acetylcholine content of the brain bears an inverse relation to the degree of prevailing activity; an increase in the acetylcholine content of the brain after administration of a number of central depressants may be a result of the decreased utilization of neurohormone in the depressed brain<sup>7,11,12</sup>.  $\alpha$ -Methyl dopa was also found not to possess any anticholinesterase activity, because it failed to potentiate the acetylcholine response of frog rectus muscle. Thus it appears that the action of  $\alpha$ -methyl dopa, like that of reserpine, involves not only depletion of sympathetic transmitter but probably also facilitation of parasympathetic activity.

### Decreased Concentration of Tissue Cortisol in the Menopause by a New Micromethod

DETERMINATION of plasma cortisol (hydrocortisone) with spectrophotofluorometric techniques has been possible as routine for the last 4–5 yr. No method has been available for the quantitative measurement of cortisol in small tissue samples, however. In our research on drug effect on cortisol metabolism and distribution we have recently devised a spectrophotofluorometric micromethod which allows quantitative determination of cortisol in tissue samples of 40–70 mg. This method may be readily adapted to material obtained by needle biopsy from skin and subcutaneous connective tissue.

This is a preliminary account of the procedure, which involves obtaining skin and subcutaneous tissue from the gluteal region by needle biopsy. The tissue is homogenized with sand, washed with petroleum benzene and transferred to alkalized dichloromethane. After evaporation at 43°–45° C with nitrogen, water and tetrachloromethane are added. The tissue is then washed twice with tetrachloromethane for quantitative removal of corticosterone and the cortisol phase is transferred to dichloromethane and finally to the fluorescent reagent, a mixture of ethanol and sulphuric acid. The fluorescence is measured using microcells (50  $\mu$ l.) in an 'Aminco Bowman' spectrophotofluorometer (excitation wavelength, 468 m $\mu$ ; emission wavelength, 524 m $\mu$ ). The amount of cortisol is calculated from a standard curve obtained by measurements of standards similarly treated.

To avoid variations caused by the considerable diurnal fluctuations known to be present in the plasma and possibly in the tissue, plasma and tissue were sampled at approximately 7.30 a.m. The samples were obtained from thirty female and thirty-two male patients selected from a general medical ward. Obese patients, those with endocrine disorders, and those undergoing hormonal

therapy were excluded from this study. The results are presented in Table 1. The average concentration of plasma cortisol showed no significant variation with age or sex, but individual variations were considerable. These data are in agreement with the results of other investigators. In contrast, the tissue concentrations of cortisol show a marked decrease in females aged 37-51, that is, the menopausal years. Only a few patients in this group had "normal" or high tissue concentration of cortisol. There was a statistically significant difference between this group and the other two groups of females ( $P < 0.05$ ). No such difference was noted in males.

The present work offers evidence that tissue levels of cortisol are decreased in a state of presumed oestrogen deficiency. It has been known previously (for references see Plager, Schmidt and Staubitz<sup>1</sup>) that the exogenous administration of oestrogens and the increased oestrogenic activity of pregnancy are associated with increased plasma cortisol levels, protein bound as well as unbound. There have been no signs of hypercorticism, however, and consequently concentrations of cortisol in tissue were presumed to be within normal concentrations. As stated by Plager *et al.*<sup>1</sup> the theory of a relation between unbound plasma cortisol and tissue cortisol is not consistent with all observations, and the proportion of unbound to total plasma cortisol may be of greater importance, but there have been no direct investigations of concentrations of cortisol in tissue. The present observations do suggest that concentrations of cortisol in tissue are dependent on oestrogenic stimulation and this requires further investigation. The mechanism is obscure; our results, however, confirm that measurement of the total concentration of plasma cortisol does not give a correct impression of the concentration of cortisol in peripheral tissues; for example, in the connective tissue of the skin.

## PSYCHOLOGY

### A Singular Lack of Incidental Learning

MORE than 200 people have been asked to recall the positions of the letters on a telephone dial, including all the staff of the Applied Psychology Research Unit (APRU), and not one has succeeded in performing the task. 151 of these people were tested formally and will accordingly be termed "subjects". The subjects were

first given a sheet of paper on which were inscribed ten circles arranged in the pattern of the telephone dial and were requested to fill in the digits. Following this they were given a sheet with a further dial with the digits correctly inscribed. On this they were requested to fill in the letters. If, as many subjects claimed, they had no idea at all where the letters were, they were requested to guess, or, in the extreme, to design their own telephone dial. Finally, a recognition test was given comprising twelve dials which had either been popular responses in preliminary tests or seemed plausible. All but one of these were required to be eliminated. The subjects, mostly members of the APRU Subject Panel, were divided into two groups, the smaller group consisting of people who had recently lived in London or had employment as switchboard operators. This sub-group was supplemented by a group from Birmingham and constituted a sample of forty-five "experienced" subjects who frequently use the letters when making local or trunk calls. The "normal" group contained 106 subjects, forty-seven of whom had no telephone in their homes.

Thirty-five of the normal group (30 per cent) and five of the experienced group (11 per cent) reproduced the digits incorrectly. Twenty-two of these began with 0 in place of 1 and moved all the digits up, and eighteen put the digits clockwise, eleven with 0 in the correct place. A slightly higher proportion of those without telephones in the normal group mistook the digits.

No one succeeded in correctly recalling the letters. Partial learning was estimated by considering the following features of the letters on a dial:

(a) they are ordered and run anti-clockwise, largely in threes (termed hereafter "admissible"); (b) O goes with 0—(O); (c) I has no letters with it—(I); (d) Q goes with 0 (on some dials it is absent)—(Q); (e) Z is absent—(Z).

Seven of the experienced group (15.5 per cent) and forty-one of the normal group (38.6 per cent) did not fulfil condition (a) and were excluded from the further analysis. They included three subjects who wrote

① ATU; ② BSV; ③ CRW; ④ DQX; ⑤ EPY;  
⑥ FOZ; ⑦ GN; ⑧ HM; ⑨ IL; ⑩ JK; which

has a pleasant if unusual pattern, and nine subjects who had the letters running clockwise but otherwise ordered. Of the remainder the number who correctly recalled the features are given in Table 1.

Table 1

	Total No. of subjects	Admissible	No. with feature correct				Total No. of features correct
			0	1	Q	Z	
Normal	106	65	12	4	5	10	31
Experienced	45	38	16	6	4	10	36

As expected, the experienced group produced a higher proportion of admissible dials, and had a higher proportion of the features correct.

In the recognition test two of the twelve examples were termed "correct", one with and one without the Q. Only ten of the normal group selected one of the correct responses, compared with nine of the experienced group. Neither of these figures differs significantly from chance. Half the recognition dials had no letters in the digit 1 position, but only thirty-three of the normal group selected one of these. This is significantly less than chance ( $P < 0.001$ ). Twenty of the experienced group recognized this feature. Eight of the twelve dials had O with 0, but only forty-four of the normal group selected one of these dials compared with thirty-one of the experienced group. The normal group again performed worse than chance ( $P < 0.001$ ). It would seem, then, that despite any residual memory the Post Office dials are not as the population would expect.

Subjects were asked to indicate their confidence in their responses to the recognition and recall tests by writing a digit from 1 for complete confidence to 5 for certainty that the response was incorrect with three intermediate categories of variable uncertainty. Sixty-three of the normal group were certain that their responses in the recall task were incorrect; no subject wrote 1. In this group only two subjects were confident they had recognized the correct dial (both unjustifiably); seventeen were certain they were incorrect. Seven of the experienced group were confident they were correct, of whom three in fact were.

One of the observations for which proponents of reinforcement theories of animal learning have difficulty in accounting is that animals appear to learn without motivation<sup>1</sup>. Another observation which old-fashioned behaviourists find unreasonable is that monkeys will perform complex tasks merely to be allowed to look out of a window—to satisfy their general curiosity<sup>2</sup>. It is thus of some considerable theoretical interest that so many people are incapable of recalling the layout of the digits of a telephone dial and that an almost negligible proportion of those tested were able to recall even individual features of the letter distribution or to recognize these features. It is clear that memory for the letters is better among those who, as a group, most frequently use them, but even this group performs badly in view of the amount of experience they must have had. For reasons of incidental learning or curiosity, better performance might have been expected. One possible explanation of these results may lie in the amount of time it takes for the dial to return to the resting position. In this time one can search for the next letter or digit and anticipation may in fact be a hindrance.

### Monocularly Evoked Electroencephalogram Potentials: Influence of Target Structure presented to the other Eye

THE average evoked electroencephalogram potentials (EP) in humans are reduced in amplitude if the flashing target is structured instead of uniformly illuminated<sup>1</sup>. Furthermore, if the flashing stimulus is presented to one eye, the EP is decreased when the other eye sees a steadily illuminated target instead of a dark field<sup>2,3</sup>, or when the image moves instead of remaining stationary on the retina<sup>2</sup>. These effects were attributed to the increased complexity of the presentation, which absorbs more cortical capacity and leaves less to participate in the evoked response. The question arises whether the EP elicited by monocular

flash stimulation is sensitive enough to reveal changes related to the target structure presented to the other eye.

A troposcope was used to present light flashes generated by a sound-shielded Grass stroboscope to the right eye at a rate of 3.6/sec. The flashes illuminated a circular diffusing area subtending 20° in the visual field. This stimulus remained constant for all viewing conditions, except that the lamp was operated at different intensities depending on the tolerance of each subject. The ancillary optics reduced the light intensity by a factor of 1,000. The other arm of the troposcope presented to the left eye a 20° circular target continuously illuminated by tungsten light. The luminance in the plane of the pupils was 0.3 mlamberts. The left and right target areas were aligned so that they appeared superposed. Four different circular targets (three only with some subjects) were used—a blank field, a central black dot, an erect cross, and an erect grid of seventeen equally spaced lines along each axis. The dot and the lines all subtended 5 min of arc. The subjects were instructed to fixate carefully the centre of the left target. The targets were presented in sequence, each for 45 sec, and an interval of 100 sec was allowed for recovery after each run; during this period the subject was responsible for changing the target. Each target was shown at least five times during one experimental session. The results were collected and processed for seven female subjects (22–28 years of age). All the results presented here were collected from one experimental session with each subject. During the session, the subject was alone in a darkened sound-attenuating room with a constant background of pseudo-white noise. The pupil of the right eye was maximally dilated and both eyes were adapted for 30 min to the low ambient level of illumination in the room.

Beginning 15 sec after the start of the repetitive light flashes, 100 amplified EP were averaged from parieto-occipital electroencephalogram leads from each hemisphere in two channels of a CAT computer. The averaged results were then transmitted to a digital computer for processing.

The EP averaged during bilateral stimulation can be influenced by many experimental conditions; changes of vigilance and attention on the part of the subject are important, as is the significance of the flashing target. The flash parameters can be rigidly controlled, and vigilance and attention can be maintained at a fairly constant level in co-operative subjects by complete regularity of experimental regime, shielding from extraneous influences (such as sudden noises), shortening the length of each run as much as possible, and providing the subject with an active part to play in the experiment in the rest periods between runs.

Correct subjective superposition of the two images was also found to be critical; if the two images are presented to non-corresponding retinal areas, the resulting EP is quite different from that generated when the stimulus areas are superposed (Fig. 1, A and B). Accurate fixation was

The two P values in parentheses give the significance of the root mean square decrease between next neighbours. For further explanation see text.

therefore emphasized and the subjects were trained during the adaptation period. When all these controls were applied, the averaged EPs for each subject became highly reproducible (Fig. 1C).

Fig. 2 shows the mean of five averaged EPs for subject 7 in each of the four viewing conditions; the most striking feature of these curves is the overall decrease in amplitude as the amount of structure in the left image increases. We have chosen the root mean square value about the mean of the averaged EP to characterize the amplitude of each averaged EP (Table 1). Of the thirty-two neighbour-pairs which can be obtained from this table, twenty-seven show a decrease in the root mean square value as structure increases, nineteen of these being significant at the  $P = 0.05$  level or better. The five observations which show an increase are not significantly different from their neighbours at the  $P = 0.1$  level. If we were to consider decreases over intervals greater than neighbour-pairs, a much higher proportion of the observations show decreases statistically significant at the  $P = 0.05$  level. The results thus show that an increase in the structure of a steadily illuminated target presented to one eye is associated with a decrease in the amplitude of the potential evoked by a flashing light seen by the other eye.

Factors which were not stable in our experimental conditions and which might have influenced the results are:

(1) The introduction of opaque structure in the steady field decreases the mean target luminance. The maximum decrease was caused by the grid target and was equivalent to 0.15 density units. In control experiments, a similar

Fig. 1. Each trace represents the mean and its standard deviation of seven averaged potentials. Viewing conditions: A, Steady target (S) and flashed field (F) subjectively adjacent. B, Steady target (S) and flashed field (F) subjectively superposed. Fixation point indicated by a cross in the diagram; this point was chosen so that S fell on retinal areas of roughly equal sensitivity in both viewing conditions. C, Superimposed averaged evoked potentials from five experimental runs in subject 6 with blank target for the left eye.

Fig. 2. Each trace represents the mean and its standard deviation of five average evoked potentials of subject 7 (left hemisphere). A, Left eye sees blank; B, left eye sees dot; C, left eye sees cross; D, left eye sees grid.

decrease in luminance of the blank target gave no consistent changes of the EP, but a further decrease of 0.40 density units resulted in increased EP amplitudes, thus exerting an effect in a direction opposite to that of the grid.

(2) Each of the steadily illuminated targets imposes a slightly different visual task on the subject. The subjects ranked the targets into two groups for ease of viewing: dot and cross were judged to be easy, while blank and grid were difficult. This would seem to arise from the problems of fixating the centre of an unstructured or a highly redundant area. If this introduced a major artefact into the results we would not expect to find the EPs for the blank target and the grid target at the extremes of the scale.

(3) Suppression and dominance between the two eyes may contaminate the results. In fact, the subjects reported spontaneous fading and reappearance of the left eye target on various occasions. However, we have not found differences between the monocular EP recorded during perceptual fade-out or visibility of a stabilized retinal image presented to the other eye<sup>2</sup>; further, it has been shown that the configuration of the evoked response is constant regardless of which eye dominates perceptually<sup>3,4</sup>.

We conclude, therefore, that the EP elicited by monocular flash stimulation is an index of the loading imposed on the visual areas by the structure of the steadily illuminated target seen by the contralateral eye.

This investigation was supported in part by grants from the US Public Health Service Department of Health, Education and Welfare. We thank Dr A. Morris for her co-operation.

## BIOLOGY

**Unique Synergistic Effects produced by the  
Principal Sex Attractant Compounds of  
*Ips confusus* (LeConte) (Coleoptera:  
Scolytidae)**

THERE is a powerful assembling scent or sex attractant in the frass produced by the male of *Ips confusus* boring in ponderosa pine (*Pinus ponderosa*)<sup>1</sup>. These attractants evoke the concentration flight or mass attack by individuals of both sexes<sup>2</sup>, but the females are much more responsive than the males<sup>3,4</sup>. When the insects arrive at the source of the attractant, they take part in boring, feeding, mating and oviposition.

Recently, three terpene alcohols that are believed to be the principal components of the attractant were isolated from male frass<sup>5</sup> and identified<sup>6,7</sup> and synthesized<sup>7</sup>. These compounds are:

I: (–)-2-methyl-6-methylene-7-octen-4-ol

II: (+)-cis-verbenol

III: (+)-2-methyl-6-methylene-2,7-octadien-4-ol

In a laboratory bioassay, a mixture of compound I with either II or III evoked a response from female beetles<sup>7</sup>, as did a mixture of all three compounds. The individual compounds were not attractive.

Field tests of isolated compounds I and III and synthetic compound II were begun on June 9, 1966, at the University of California Blodgett Research Forest, Eldorado County, California. The three compounds, individually and in various combinations, were presented together with a benzene extract of frass to flying populations on packets of filter paper placed on aluminium foil in the centre of 1 ft.<sup>2</sup> masonite boards covered with 'Stickum Special'. Attractive male frass was also presented in the same way by placing it under screens of plastic mesh in Petri dishes. The packets and frass were renewed at hourly intervals to compensate for the loss of attractants by volatilization and for variations in the diurnal flight of the beetles. The boards were spaced about 25 ft. apart with no particular attention to exposure. A minimum of two replications was used for each test. All materials were presented in the amounts found in 1 g of male frass (I, 125 µg; II, 2.5 µg; III, 12.5 µg).

The combination of compounds I, II and III evoked the most potent response; the entire catch (fourteen males and eighteen females) occurred within about 20 min on the one day it was tested. Compounds I and III together attracted four females only. The beetles attracted to frass (fourteen males and forty-five females) and frass extract (twelve males and twenty-one females) were trapped over a period of 2 days. Compounds presented individually and in other combinations failed to attract a single specimen of *I. confusus*. Surprisingly, *Ips latidens* (LeConte) was attracted to compound I alone (five females) and to a combination of I and II (three males and thirty-four females). No bark beetles were trapped on the blank control boards.

After this unexpected development, *I. latidens* was exposed to all the synthetic compounds both individually and in combination, in the laboratory olfactometer. Compound I alone (20 µg), and in combination with II, definitely affected the behaviour of both sexes. The response to compound I alone is best described as an arrestant; the beetles circled very slowly in the air stream and some males eventually traversed to the receptacle containing the attractant compound. The characteristic klinotaxis<sup>8</sup> was not observed, however. Compounds I and II (2.0:0.1 µg) did evoke the typical klinotaxis, moderately for the female, weakly for the male. No response was elicited by the combination of I and III and by III alone. Compound II alone and II

with III at 10 µg each evoked at most a weak response. But when 0.1 µg of compound III was added to 2.0 µg of I and 0.1 µg of II, the attraction for *I. latidens* was eliminated. This combination proved highly attractive to *I. confusus*, however, even at one-tenth this concentration.

The unusual synergistic system obtained by adding compound III to the combination of I and II, which blocked or masked the *I. latidens* attractant and created the *I. confusus* attractant, poses some challenging chemical and biological problems. We are at present comparing the chemical fractions of *I. latidens* frass with those of *I. confusus*.

These studies demonstrate the deviations between laboratory and field evaluations and emphasize the necessity of using both bioassays to identify pheromones.

### Volatility of Trail Marking Substance of the Town Ant

WE have found that the trail marking substance laid down by the town ant, *Atta texana* (Buckley), contains at least two components, one volatile and the other non-volatile; both are followed by workers. Both components partition into the organic phase of a methylene chloride water system.

Poison sacs from five medium-sized workers were crushed in 1 ml. of methylene chloride, and the solutions were dispensed with a pipette on circles 14 cm in diameter drawn on smooth cardboard. Polyethylene plastic sheets 0.13 mm thick were placed 0.1, 1, 2 or 4 cm over these artificial trails on solid circumferential spacers, thereby creating a closed air space between trail and plastic sheet. Holes were punched in the sheet directly above the trail with a No. 1 insect pin. For most tests, eight holes per cm were punched in each of two parallel rows 1.5 mm apart (about the distance between antennae of a minor worker).

In each test, five minor workers were released on the plastic sheet in the centre of the circle. After 10 min, actions of ants that responded were classed as (1) circling, when at least one worker travelled the entire circumference of the circle (44 cm); (2) partial circling, when a worker travelled only part of the circumference; and (3) detecting only, when workers briefly oriented toward a hole but did not follow the trail. The last two conditions were accompanied by zigzagging as the ants alternately found and lost the scent.

Height above the trail, distance between holes, and trail age affected insect behaviour. The ants circled as high as

2 cm and one partially circled at 4 cm. Workers circled when holes were spaced as far apart as 1 cm.

Response was maximum when plastic sheets were positioned immediately after trails were made. When sheets were spaced at 1 mm, workers circled a 30 min old trail in the arbitrary period of 10 min. If the sheet was laid over the trail after 45 min, they only partially circled in the same amount of time. Little if any response occurred after 60 min. Some of the volatile substance remained, however, because workers easily circled trails that were 120 min old when the plastic sheet had been placed 60 min before the bioassay. Apparently, this gave the volatile fraction time to accumulate sufficient vapour pressure under the plastic to trigger a response by the ants.

At a height of 2 cm, ants circled only if the plastic sheet was positioned within 3 min. They partially circled when the sheet was placed after 5 min, but they did not respond when it was placed after 10 min.

The non-volatile fraction gradually decomposed, probably by oxidation. Workers circled on artificial trails that had been kept in darkness at room temperature for 6 days, but only partially circled trails kept for 12 days. In contrast, trails were circled that had been held under a vacuum of 0.4 mm of mercury for 4 months.

The ants always laid a natural trail on the plastic as they detected the artificial trail below. Other ants followed both the volatile and non-volatile fractions of natural trails when sheets were removed from artificial trails. Thus, the number of workers that followed the volatile material was meaningless for statistical purposes. The trail reinforcing behaviour is in contrast to observations in the field where workers seldom touched their abdomens to the trail<sup>1</sup>.

Workers of *Trachymyrmex septentrionalis* (McCook) readily circled 1 mm above the artificial trail of *Atta texana*, and on the trail itself after it had been held in a vacuum of 0.4 mm of mercury for 3 days. Thus neither fraction is the species specific substance postulated by Blum *et al.*<sup>2</sup>. *T. septentrionalis* workers also laid a natural trail on the plastic.

In another test, five sacs of *Atta texana* were crushed in 1 ml. of methylene chloride, and the solution was thoroughly extracted with six 1 ml. portions of water. A trail prepared from the extracted solution elicited a circling response at a height of 1 mm; after 2 days under a vacuum of 0.5 mm of mercury the trail was circled by workers in direct contact with it. The first aqueous extract was in turn extracted with five 1 ml. portions of methylene chloride. A trail prepared from the aqueous solution elicited only a very feeble response from workers placed in direct contact with it and no response from workers above it.

### Forked Tail of the Cercaria of *Schistosoma mansoni*—a Rowing Device

THE swimming motions of the cercaria of *Schistosoma mansoni* have been analysed by high-speed photography, at a rate of 500–800 pictures/sec. When cercariae swim backwards the two branches of the forked tail are spread out (Fig. 1a and b), while in forward-swimming cercariae the branches are close together (Fig. 1c and d). Without

significantly altering the stroke rate of the tail, cercariae can change from backward swimming to forward swimming, or the reverse, depending on how they align the branches of the tail. When changing from backward swimming to forward swimming the cercaria lengthens its body by 30–40 per cent (Fig. 1c and d) and at the same time makes itself narrower.

When swimming backwards the cercaria has two constrictions, which are not present when it is swimming forwards. One of the constrictions is between the fork and the stem of the tail, and the other is at the end of the body near the base of the tail (Fig. 1a and b). These two constrictions have the function of joints.

In the tail stem there are between forty and forty-eight longitudinal muscle elements with distinct transverse striations. The longitudinal muscles of the left and right side contract alternately and in turn bend the tail stem from one side to the other. The rate of oscillations of the tail in ten cercariae swimming backwards ranged from 20.7 to 23.7 sec, mean value 22.1, and in cercariae swimming forwards it was 20.9–23.6 (mean value, 22.5)/sec. The shape and poise of the body and the fork of the tail determine whether the cercaria swims forwards or backwards. Smooth muscles (also circular muscles) seem to effect these changes in shape and poise. Fig. 2 shows the behaviour of the body and the branches of the fork, which resemble oar blades, when the stem of the tail is active. Seventeen successive phases during one stroke of the tail are shown as the cercaria swims backwards. The centre line through the cercaria is shown in the position it would occupy at 1.6 mm/sec intervals. In Fig. 2 a body and its fork are in a more relaxed position after having been deflected by the resistance of the water during the preceding stroke. In Fig. 2b the fork is carried upwards at an angle of incidence which permits only slight propulsion, and in Fig. 2c the fork is driven downwards producing a considerable backward thrust. By this movement body and fork are now deflected in the opposite direction and in Fig. 2d they return to a more relaxed position.

Fig. 1.

Fig. 2.

Not only the fork of the tail but also the body of the cercaria can produce a weaker propulsion and a stronger backward thrust (Fig. 2b). In this case the body works on the principle of the fish-tail, but bending is largely replaced by oscillation around a joint-like area. As the cercaria swims forward (Fig. 1c and d) the folded fork branches function like an elastic tail fin. The connexion between body and tail has lost its flexibility and is now actually rigid. As a result of new properties of resistance a wave passes along the cercaria from the body to the tail end with all striated muscles equally active (Fig. 1c and d). This results in propulsion. The maximum speeds for animals swimming backwards or forwards are 1.4 mm/sec; the distance covered in 1 sec corresponds to about three body lengths.

Swimming backward and forward by means of an adjustable forked tail has been reproduced in a model (built by H.-G. Beckmann and called "Cercaria I"). A forked tail made of rigid material with a joint as in Fig. 1f is sufficient to produce backward movement which can be converted to propulsion and vice versa, even in the model, by folding backwards the branches of the transverse oar blade and by retaining the limited range of the joint (Fig. 1g). Models of this kind could perhaps be applied to mixing tasks and driving mechanisms in engineering.

### Decrease in Eggshell Weight in Certain Birds of Prey

THE incidence of broken eggs in nests of peregrine falcon *Falco peregrinus*, sparrowhawk *Accipiter nisus* and golden eagle *Aquila chrysaetos* in Britain has increased considerably since 1950. In 109 peregrine eyries examined in 1904-50, there were only three instances of egg breakage, compared with forty-seven in 168 eyries examined in 1951-66. Two of thirty-five golden eagle eyries examined in 1936-50 contained broken eggs, compared with twelve out of forty-eight examined in 1951-63. One breakage was found in twenty-four sparrowhawk nests in 1943-50, but eight in twenty-seven nests in 1951-60. Peregrines have been witnessed eating their own eggs<sup>1</sup>, and most recent egg breakages in all three species appeared to involve parental destruction.

Eggshell thickness was investigated by measuring weight and size of blown eggs of varying age, using

specimens cleanly emptied through a hole not exceeding 7 mm in diameter, thus rejecting heavily incubated eggs. In peregrine and sparrowhawk, eggshell weight/size ratio decreased significantly and suddenly in 1946-50, and has not recovered. Since 1947, the only "normal" peregrine eggshells were four of the seven available from the East Highlands. After 1946, sparrowhawk eggshells from Surrey were significantly lighter than those from Cumberland, Dorset and Hampshire. Golden eagle eggshells from West Scotland are slightly yet very significantly lighter but East Highland eggshells remain unchanged. Fewer golden eagle eggs were available, but change during 1945-50 is again indicated.

The eggshells as measured consisted largely of calcium carbonate (about 90 per cent in "normal" eggs), the remaining fraction being shell protein<sup>2</sup>, adherent shell membranes, and residual film of contents. The decrease in eggshell weight has involved mainly the calcium carbonate fraction. Decrease in shell thickness rather than density is implied, but this has not been measured directly.

Thickness of eggshells and production of eggs vary according to diet (especially calcium) and condition in poultry; eggshell thickness is also genetically influenced, and diminished by disease and increasing age<sup>3</sup>. Certain chemicals, for example sulphanilamide<sup>4</sup>, cause decrease in eggshell thickness, as can stress; severe fright can stop poultry laying for a time. Occasional thin-shelled eggs may be laid by any wild bird species, but before 1946, mean eggshell weight and size for clutches from the same female raptor, year by year, were fairly constant, though weight/size of eggshells within one clutch was less consistent.

Decrease in eggshell weight in peregrine and sparrowhawk was synchronous, rapid and widespread. It occurred in successive clutches of the same female peregrines at four different eyries, but three other females laid at least one clutch of normal weight after they had produced light eggs. General ageing or genetic shift in the population are thus not likely to be involved, while the synchronous effect on three raptors with different ecology and distributions, and the varying geographical response, make disease an unlikely explanation.

Decrease of calcium carbonate for eggshell formation could result from reduced food consumption, but no decline in available food supply for these raptors was known in 1940-50. Loss of hunting efficiency could cause an effective food shortage, or change in metabolic regulation could induce internal shortage of calcium, without less food being consumed. A different possibility is premature extrusion of eggs, known in poultry (personal communication from C. Tyler).

Some physiological change evidently followed a widespread and pervasive environmental change around 1945-47. Increasing radioactive contamination fails to account for geographical variations in eggshell change, whereas these match the developing regional pattern of contamination by chemical pollutants during this period. Among urban-industrial pollutants, one waste product in smoke, the persistent polychlorinated biphenyl (PCB), has been found in tissues of fish, eagles and humans in Sweden, and was first detected in 1944 in an eagle<sup>5</sup>. There was a notable boom in organic insecticides, fungicides and herbicides containing chlorine, mercury, phosphorus and sulphur after 1945, and environmental contamination by persistent residues has been widespread<sup>6</sup>. British peregrines, sparrowhawks and golden eagles have shown widespread contamination by *pp'* DDT, *pp'* DDE,  $\gamma$ -BHC, dieldrin and heptachlor epoxide<sup>7-9</sup>. The introduction of

Fig. 1. Change in the ratio of weight to size (index of thickness) in eggshells of the peregrine falcon in Britain. Circles represent eggshells from the central and eastern Scottish Highlands, and dots represent eggshells from other districts (see Table 1).

Fig. 2. Change in the ratio of weight to size (index of thickness) in eggshells of the sparrowhawk in Britain. Circles represent eggshells from south-eastern England, and dots represent eggshells from other districts (see Table 1).

DDT into general use (about 1945–46) coincided closely with onset of the eggshell change. Dieldrin, aldrin and heptachlor appeared 10 yr later and, like DDT and  $\gamma$ -BHC, have been used extensively ever since. Contamination of birds by persistent organo-mercury compounds has received little attention in Britain, but in Sweden the introduction of these as seed dressings paralleled the substantial increase in mercury content of raptor tissues during the 1940s (ref. 10).

Calcium metabolism in birds is controlled by oestrogen and parathyroid hormone<sup>3</sup>, and is thus potentially sensitive to any chemical disturbing hormone regulation. Jefferies<sup>11</sup> has demonstrated a significant correlation between intake of *pp'* DDT by the Bengalese finch *Lonchura striata* and delay in ovulation, and interprets this as a hormonal effect. One dithiocarbamate fungicide affects eggshell thickness in poultry<sup>12</sup>, but is non-persistent and of unknown relevance to raptors.

The time correlation between decrease in eggshell weight and increase in egg-breakage suggests a causal con-

nexion. In the peregrine and golden eagle there is also geographical correlation, for in the East Highlands decrease in eggshell weight is slight or unknown and egg breakage unusual. Eating eggs is probably an instinctive adaptive response to unfavourable circumstances arising after laying, and seldom invoked before 1946. Other bird species normally eat or destroy their damaged eggs<sup>13</sup>, and lighter raptor eggs are probably more prone to accidental damage than "normal" eggs. Yet, often, raptors have evidently destroyed undamaged eggs, perhaps in response to a calcium "hunger". Domestic fowl which have broken and eaten an egg often develop an incurable appetite for their eggs. While calcium is obviously implicated, in several raptor instances the egg contents had been eaten and most of the shell left.

Other bird species in which egg-breaking is unusual (hobby *Falco subbuteo*, merlin *F. columbarius*, buzzard *Buteo buteo*, carrion crow *Corvus corone*, golden plover *Charadrius apricarius*, greenshank *Tringa nebularia*, guillemot *Uria aalge*, and razorbill *Alca torda*) show no

change in eggshell weight. In kestrel *F. tinnunculus* and raven *Corvus corax*, the eggs of some individuals show a slight decrease, but not the whole population samples.

For the species examined, frequency of egg-breakage, scale of decrease in eggshell weight, subsequent status of breeding population, and exposure to persistent organic pesticides are correlated. The possibility that these phenomena are links in a causal chain is being investigated. Recovery of locally depleted populations of peregrine began in 1946 and continued for several years after eggshells became lighter and egg eating frequent, even in districts, such as Dorset, where both changes were obvious. Population "crashes" in peregrine and sparrowhawk after 1955 probably involved greatly increased adult mortality, but later factors contributing to low breeding success would tend to prevent recovery.

### Moisture Sensitivity, Mechanical Injury and Gibberellin Treatment of *Beta vulgaris* Seeds

"RUBBING" ("shearing") is a mechanical process used to separate the fruit clusters of *Beta vulgaris* L. (sugar beet or beetroot) into more or less even-sized segments, each with one or two seeds, by grinding away some of the hard tissue surrounding the seeds with an assembly of

abrasive disks. The investigation here reported followed the almost complete failure of a rubbed sample of beetroot seeds to germinate in a field in which a different rubbed sample of the same cultivar ('Detroit Globe'), sown at the same time, germinated satisfactorily. Neither sample contained any obviously damaged seeds and no damage was found when embryos excised from imbibed seeds were examined under the microscope. Natural (unrubbed) seeds from the same sources (Lot 1, good; Lot 2, bad) were later obtained. In a series of laboratory experiments we found that: (1) Germination of unwashed seeds can be depressed by insufficient moisture (Fig. 1A). (2) When beetroot seeds are washed and then immediately placed on wet filter paper scarcely any will germinate; but if they are washed, dried and then placed on moist filter paper they germinate well (Table 1). (3) Similarly, germination can be depressed when seeds are placed on a substrate which is even slightly wetter than necessary (Fig. 1); this effect is particularly pronounced with unwashed seeds (Fig. 1A) but can be alleviated by adding small quantities of hydrogen peroxide (Table 2). Warburg respirometer results show that the respiration of beet seeds is appreciably suppressed in a slight excess of water. (4) Natural seeds from Lot 2 germinate at least as satisfactorily as seeds from Lot 1, but rubbing depresses the performance of seeds from Lot 2, though not of those from Lot 1 (Fig. 1B). (5) Shaking the seeds for 45 min in a glass bottle has an effect on germination similar to that

Table 1. EFFECT OF DRYING AFTER WASHING

of rubbing (Fig. 1C). (6) Soaking the seeds in 4 p.p.m. gibberellin, followed by drying, lessens the effect of a certain level of excess moisture on germination, especially of rubbed or shaken seeds (Figs. 1C, 1D). (7) In the triphenyl tetrazolium chloride (TTC) test, in which intact cells stain red because of their dehydrogenase activity and damaged cells remain unstained, embryos from intact beetroot seeds are stained uniformly, but embryos from rubbed and shaken seeds are not. On the other hand, treatment of rubbed or shaken seeds with 4 p.p.m. gibberellin largely restores the capacity of their embryos to stain red (Table 3) in response to TTC.

Table 3. 2,3,5-TRIPHENYL TETRAZOLIUM CHLORIDE TEST OF EXCISED BEETROOT SEEDS (LOT 2)

Seed treatment	Gibberellin	No. of embryos assessed	Per cent "non-viable"
Natural	None	166	4
Rubbed	None	106	30
Rubbed	4 p.p.m.	106	18
Shaken	None	259	40
Shaken	4 p.p.m.	259	14

\* "Non-viable": embryos only partially stained or unstained.

These results confirm that natural *Beta* seed clusters contain a water-soluble inhibitor<sup>1,2</sup> the effect of which is diminished either by leaching or by removal of cluster material during rubbing<sup>3,4</sup>. But our results further suggest that: (1) Germination is impeded by excess moisture, owing to interference with respiration. (2) The effects of the soluble inhibitor in the cluster material are particularly pronounced (a) when the moisture supply is limited, but also (b) under the influence of excess moisture, even though the moisture must have diluted the inhibitor. This suggests an interaction of inhibiting principles, that is, that the restriction of oxygen supply renders the embryos more sensitive to the inhibitor in the cluster material, or *vice versa*. (3) Impact by rubbing or shaking causes damage which interferes with the dehydrogenase activity of the embryonic cells and tends to depress germination; in particular, it accentuates the detrimental effect of excess moisture. (4) Addition of gibberellin (a) restores the dehydrogenase activity, and (b) to some extent compensates for the effect of restricted oxygen supply and thereby enables the seed to germinate under

wetter conditions. The mechanisms involved are not clear at present.

We thank Dr R. G. Hiller for helpful advice.

## Sexual Factor of the Mucorales

BURGEFF<sup>1</sup> was the first to produce evidence of the formation of a sexual factor by mated strains of the fungi *Phycomyces blakesleeanus*, *Mucor mucedo* and possibly all other members of the Mucorales. This substance, which is produced in very small amounts, is held responsible for the induction of the formation of gametangia. It appears that it is not species specific, for *M. mucedo* exhibits a positive reaction with preparations obtained, for example, from *Blakeslea trispora* as well as from *P. blakesleeanus*. Plempel<sup>2</sup> supposed that the sexual factor is a mixture of two substances that are produced by the plus and the minus strain of the fungus respectively.

We have obtained a substance showing the sexual activity described from shaken cultures of mated strains of *B. trispora* in a potato-glucose medium. It was isolated according to the method of Plempel<sup>2</sup>, identified and characterized by bioassay<sup>3</sup>, paper chromatography (Whatman No. 1; *n*-butanol saturated with 0.05 normal ammonia), and ultra-violet spectroscopy. The procedure used was as follows. The acidified medium of a 5 day old culture was extracted with diethyl ether. The extract was next fractionated by partition chromatography on a column of 'Hyflo Supercel' impregnated with 0.3 molar phosphate buffer, pH 7.7. The column was developed

\*  $R_F$  values of ultra-violet absorbing spots on a paper chromatogram (Whatman No. 1, *n*-butanol/0.05 normal ammonia).

† Half value potentials of polarographic waves of solutions in 1 per cent tetra-*n*-butyl ammonium hydroxide of the components that are obtained by elution with dilute alkali of the corresponding spots on the paper chromatogram. The polarographic behaviour at potentials more negative than -1.8 V was not investigated.

‡ Biological activity was determined towards the plus and minus strain of *Mucor mucedo*.

§ The polarogram of component No. 4 also has a small wave at -0.8 V and -1.50 V, attributable to impurities, for further purification on DEAE-'Sephadex' results in a biologically active preparation that gives only one wave at -1.35 V.

with hexane, benzene and diethyl ether, successively; the biologically active substance was eluted with the third solvent. Paper chromatography of this fraction separated at least five ultra-violet absorbing components of which only that with an  $R_F$  value of 0.65 was biologically active (Table 1). When this single spot was eluted with dilute alkali and rechromatographed on paper the same set of five components was obtained, so that considerable decomposition seems to take place during the isolation procedure.

It is possible to distinguish between the biologically active compound and decomposition products by d.c. polarography, using tetra-*n*-butyl ammonium hydroxide as supporting electrolyte (Table 1). This method is very suitable for relative determination of the sexual factor in partially purified extracts. It can be further purified by chromatography on DEAE-'Sephadex' with a concentration gradient of pH 9.0 *tris* buffer (Fig. 1).

The most important outcome of the experiments so far is that no indications whatsoever have been found for the occurrence of two biologically active substances, that is one active on the plus strain and the other active on the minus strain of the fungus.

More careful examination of the absorption in the near ultra-violet region revealed, however, that the isolated compound is probably a mixture of *cis* and *trans* isomers. After purification by chromatography on DEAE-'Sephadex' its ultra-violet absorption spectrum had maxima at 230 and 325 m $\mu$ . When a sample of a solution in ethanol was exposed to strong light from a fluorescent tube, the maximum at 325 m $\mu$  was much reduced and shifted towards a shorter wavelength, whereas the maximum at 230 m $\mu$  was slightly increased. If a catalytic amount of iodine was added and the sample exposed to light again there was a strong and rapid increase of the optical density at 310-325 m $\mu$ . The final absorbancy was considerably greater than that of an unexposed sample. If the latter was exposed to light in the presence of iodine, exactly the same absorbancy was obtained (Fig. 2). The reversibility of the spectral changes was a strong indication

Fig. 1. Gradient chromatography on DEAE-'Sephadex' G-25 of a sexual factor isolated from the culture medium of mated plus and minus *Blakeslea trispora*. This procedure was preceded by extraction and partial purification by partition chromatography on 'Hyflo Supercel' (see text). The dimensions of the column were 47 x 1 cm. Linear concentration gradient of *tris*-hydrochloric acid buffer pH = 9.0, of ionic strength 0.01-0.1; total elution volume 1,000 ml. The concentrations at which the components were eluted are indicated in the figure. The sexual factor was eluted at the concentration of 0.065.

Fig. 2. Ultra-violet absorption spectrum of a solution of the sexual factor in ethanol. The factor was extracted from a culture of mated plus and minus *Blakeslea trispora* and purified by chromatography on DEAE-'Sephadex'. The eluted solution (in *tris* buffer, pH 9.0) was acidified and extracted with diethyl ether. After drying of the extract over magnesium sulphate, and evaporation of the solvent in a vacuum, the residue was taken up in ethanol. The following samples were taken from one solution: —, untreated sample; ---, sample exposed to 10,000 lux from two fluorescent tubes for 0.5 h; and - · -, untreated or illuminated sample, later exposed to the same intensity for 5 min in the presence of a trace of iodine.

of the occurrence of *cis-trans* isomerism. The spectral behaviour of the present compound is analogous to that of the carotenoids where, as described by Zechmeister<sup>3</sup>, it is caused by reversible *cis-trans* isomerization. Experiments aimed at the separation of possible isomers are in progress now.

When a solution of the sexual factor was exposed to light, biological activity towards both the plus and the minus strain was much reduced. The original activity was fully restored by illumination in the presence of iodine.

Caglioti *et al.*<sup>4</sup> isolated from mated cultures of *B. trispora* a substance said to stimulate carotenogenesis in cultures of the separate strains. This substance, named 'trisporic acid C', was characterized as a hydroxy-keto acid with three conjugated double bonds. The sexual activity of many Mucorales is coupled with increased synthesis of carotenoids, and the ultra-violet absorption spectrum of this trisporic acid is very similar to that of the substance described in this communication, and so it is possible that the two compounds are identical.

## ANTHROPOLOGY

### Overkill at Olduvai Gorge

DR LEAKEY has replied<sup>1</sup> to my proposal<sup>2</sup> that the pattern of extinction of large mammals at the end of the Middle Pleistocene in Africa represents overkill by prehistoric

man. If one adopts all Dr Leakey's suggestions for updating or factually improving the African list of extinct mammals, the net effect is trivial—an increase in the number of living large genera from forty to forty-one, an increase in later Pleistocene extinction from more than twenty-six to more than twenty-nine genera, a decrease in earlier Pleistocene extinction from nineteen to eighteen genera, and an overall change in the amount of later Pleistocene megafaunal extinction in Africa, as computed in Table 3, ref. 2, from thirty-nine to forty-one per cent. I do not see how the omission of the genera Leakey adds to the Early Pleistocene group "... puts the whole picture out of balance".

As the richest single stratified fossil deposit representing the time interval in question the Olduvai record deserves special consideration. Leakey<sup>3</sup> reports twenty-one extinct genera of large mammals, presumably all from the living floors or camp sites of prehistoric man at Olduvai, five last recorded in the Upper Villafrancian, six in the Early Middle Pleistocene in strata associated with Chellean tools and ten surviving to the time of Bed IV, the unit associated with Acheulean artefacts of the late Middle Pleistocene (Table 1). Evidence of Acheulean association elsewhere indicates that at least four of the Bed II extinct genera from Olduvai, namely *Mesochoreus*, *Orthostonyx*, *Phenacotragus*, and a machairodont, may be considered contemporaries of the hand-axe fauna of Bed IV. Because Leakey reports that less is known about the fauna of Bed IV than about that of Bed I and II (ref. 3), they may yet be found. Clearly, generic extinction during the time of the hand-axe hunters far outstrips extinction during any earlier interval yet known in the African Pleistocene. How is it to be interpreted?

Table 1. LAST OCCURRENCES OF EXTINCT LARGE MAMMALS (> 50 KG) FROM OLDUVAI GORGE<sup>2</sup>

		BOVIDAE	<i>Thalerceros</i> *
			<i>Parmularius</i>
			<i>Xenoccephalus</i> †
			<i>Bularchus</i>

\* Rare (three individuals or less).

† Acheulean association elsewhere.

Dr Leakey regards drought as the cause of African extinction<sup>1,3,4</sup>. If so, it was the first catastrophic drought to strike the African fauna, and while one must believe it affected the entire continent, it was unique to Africa, an event that left no obvious mark on the megafauna of the time in other areas including Madagascar.

In his book on Olduvai, Leakey takes a restrained position on the palaeoclimatic meaning of extinct mammals<sup>3</sup>: "... it is not generally recognized that many of the larger mammals are remarkably adaptable... While zebra and giraffe are most commonly found in savannah and open plains with scattered thorn bush, they can also be found well within tropical forest zones such as those bordering Lake Manyara. These few examples serve to show how unwise it is to regard the usual habitat of large mammals as necessarily constant. If the habitat of large living mammals, belonging to a single species, varies so widely it is clear that the presence of extinct fossil species—even if related to the living forms—cannot be used as a basis for deducing ecological or climatic conditions." Thus in attributing the extinction of large

mammals of Bed IV to drought, Leakey ignores both his own advice and also the present distribution of East African mammals. Five of the largest species, elephant, hippopotamus, black rhino, giraffe, and buffalo, all occupy (or did in historic time) the desertic shores of Lake Rudolph, a region of under 250 mm rainfall, one of the driest parts of equatorial Africa.

I do not wish to deny the likelihood of droughts at any time during or after deposition at Olduvai. The point is that at Olduvai as elsewhere in the world a major episode of Late Pleistocene megafaunal extinction coincides with the prehistoric development of big game hunters. Unless a continent or island can be found in which a major wave of megafaunal extinction occurs other than soon after the arrival of man, or his cultural development as a stone age hunter, the possibility of overkill, will persist as a challenging "least improbable hypothesis".

P. S. MARTIN

Geochronology Laboratories,  
University of Arizona, Tucson.

Received March 6; revised April 3, 1967.

<sup>1</sup> Leakey, L. S. B., *Nature*, **212**, 1615 (1966).

<sup>2</sup> Martin, P. S., *Nature*, **212**, 339 (1966).

<sup>3</sup> Leakey, L. S. B., *Olduvai Gorge 1951-1961* (Cambridge Univ. Press, 1965).

<sup>4</sup> Leakey, L. S. B., *The Ecology of Man in the Tropical Environment* (I.U.C.N. Publ. No. 4, Morges, Switzerland, 1964).

It does not seem worth devoting more time, or space, to discussing that part of my argument with Dr Paul Martin, on the subject of Pleistocene overkill, which deals with percentages of genera that may have become extinct at a given point of time, or that have survived to the present day. My reasons for saying this are as follows: (a) there is too little agreement as to what constitutes a genus; (b) that even since the publication of the earlier notes by Martin and myself last year, *Bulcharus* has been made a synonym of *Pelorovis*, and it has been suggested that *Tapinochoerus* is generically identical with *Orthostonyx*. It must also be noted that the majority of anthropologists now treat *Telanthropus* as belonging to the genus of *Homo* and the others as *Australopithecus*. No one accepts it as a distinct genus. Similarly, *Australopithecus*, *Paranthropus* and *Zinjanthropus* are now all genus *Australopithecus*.

Then again, few zoologists agree on the subject of the generic classification of living genera in Africa. Some would list zebra as *Hippotigris*, not *Equus*, and the wild ass of Somaliland as *Asinus*: some would list *Theropithecus* as a distinct genus from *Papio*, others would not. Some would divide wildebeeste into two genera—*Gorgon* and *Connochaetes*—and so on. It thus seems clear that any arguments based on statistics and percentages of wholly unsure genera are of little value.

Dr Martin completely ignores the last paragraph of my communication<sup>1</sup> of December 31 in his present reply. I believe it is quite unscientific to invoke "overkill" by Acheulean hunters to explain the extinction of some forty or more genera at the end of the Middle Pleistocene when the much more numerous and much better equipped hunters who succeeded Acheulean man, during the Upper Pleistocene and post-Pleistocene time, had so little effect on the remaining fifty or more genera. I refer, of course, to the hunters of the Middle Stone Age, the Upper Palaeolithic, the Mesolithic, the Neolithic and also the Iron Age hunters. On the basis of Dr Martin's arguments, these people should have exterminated nearly all the genera which survived into the Upper Pleistocene. In fact we know that they did not.

## AGRICULTURE

### Carbonyl Sulphide from the Decomposition of Captan

VOLATILE sulphur compounds such as carbon disulphide and thiocarbonyl chloride are considered to be formed when the agricultural fungicide captan (*N*-trichloromethyl-thio-4-cyclohexene-1,2-dicarboxyimide) reacts with fungal spores<sup>1,2</sup>. During a general investigation<sup>3</sup> of the fungitoxicity of captan we have examined by gas chromatography the vapours released when captan reacts with the conidia of *Neurospora crassa*, macroconidial wild-type Em 5297a, at 25° C.

A solution of 375 µg of captan in 0.5 ml. of ethanol was added to a 2 ml. aqueous suspension of 840 million *N. crassa* spores in a 35 ml. bottle. After 20 min a 1 ml. sample of the atmosphere above the suspension was removed with a Hamilton gas syringe and injected into a 'Microtek GC.2000' chromatograph provided with a dual thermal conductivity detector. Helium at 90 ml./min was the carrier gas and the column, inlet, and detector were at 165° C: the stainless steel column was filled with the uncoated solid absorbent 'Porapak Q' (80/100 mesh size). Commercially available compounds were used as standards with the exception of carbonyl sulphide (COS) which was prepared from the reaction between ethyl isothiocyanate and sulphuric acid and further purified by the preparation and decomposition of potassium ethyl thiocarbonate<sup>4</sup>. Fig. 1 shows that carbonyl sulphide was evolved when captan reacted with *N. crassa* spores: there was no trace of carbon disulphide. Captan is rapidly decomposed by cell thiols<sup>1,3</sup> and when 750 µg of captan in 1 ml. of ethanol was added to an aqueous solution of excess glutathione, that is 3 mg, the resulting chromatogram (Fig. 2) of the vapours showed carbonyl sulphide but no carbon disulphide.

Infra-red gas analysis, in a 10 cm cell, with a Perkin-Elmer 237 spectrophotometer confirmed that carbonyl sulphide was produced from the reaction of glutathione and captan. The atmosphere above the solution was passed successively through acetone-solid carbon dioxide and liquid air traps<sup>5</sup>; the contents of the latter trap were then evaporated into the gas cell. The spectrum was identical to that of synthetic carbonyl sulphide with a doublet at 4.83 and 4.87 µ<sup>6</sup>. It was not possible to obtain sufficient carbonyl sulphide from the captan-spore reaction for infra-red analysis.

Lukens<sup>2</sup> confirmed his earlier supposition<sup>1</sup> that thiocarbonyl chloride is a major product of the reaction of captan with fungal spores—presumably following reduc-

Fig. 1. Gas chromatogram of products of reaction between captan and *Neurospora crassa* conidia.

Fig. 2. Gas chromatogram of products of reaction between captan and glutathione.

tion by cell thiols. Although we were unable to resolve thiocarbonyl chloride by gas chromatography we have found that this compound is rapidly hydrolysed by excess water to form carbonyl sulphide the identity of which was confirmed, as before, by gas chromatographic and infra-red analysis. Haszeldine and Kidd<sup>6</sup> reported a similar result, but as they used a lower water-thiocarbonyl chloride ratio the hydrolysis was much slower at room temperature. The most probable explanation for the evolution of carbonyl sulphide from mixtures of captan and fungal spores is that it is a product of the rapid hydrolysis of the thiocarbonyl chloride initially formed. A more complete discussion of this reaction is in preparation.

In view of the results of Lukens and Sisler<sup>1</sup> it seemed surprising that we could obtain no evidence of the formation of carbon disulphide from the reaction of captan with either spores of *N. crassa* or the model thiol, glutathione. These authors identified carbon disulphide by trapping the gas in Viles solution<sup>7</sup> and measuring, at 440 mµ, the intensity of the yellow complex formed. We have found, however, that carbonyl sulphide also produces a yellow compound with Viles solution that gives an appreciable absorption at 440 mµ. It is apparent that this reagent is not specific for carbon disulphide and that, as Viles<sup>7</sup> has suggested, other double bonded sulphur compounds can interfere.

The formation of carbonyl sulphide from captan has biological as well as chemical interest because it has been shown<sup>8</sup> that vapours of this compound can be appreciably fungitoxic. Captan is used as a soil and seed fungicide<sup>9</sup> and the release of carbonyl sulphide after its decomposition in the soil may well give a wider area of protection than has been previously supposed.

We thank Dr G. Nickless for the use of the gas chromatograph.

## BOOK REVIEWS

## LEARNING FROM AMERICA

## Science and the Educated Man

Selected Speeches of Julius A. Stratton. Pp. viii + 186. (Cambridge, Mass., and London: The M.I.T. Press, 1966.) 40s.

DR STRATTON spent his life at the Massachusetts Institute of Technology. He was student, faculty member, professor, provost, chancellor and president. He was moulded by one of the great universities of the world, and he influenced it profoundly throughout his professional life.

We have become accustomed to the fact that English universities usually follow the example of America. We may protest and we may delay for twenty years, but we do so in the end. MIT has inspired many other American universities. In some ways it has been the pacemaker for the world, so Dr Stratton's thoughts about the current situation and the proposals for reform which he has enunciated in this book are likely to be important to many of us now and for several decades to come. It seems probable that American universities have solved many of the problems which are worrying us today; it is quite certain that they have encountered a whole series of problems which we have yet to face.

The whole American university system has been based traditionally on the assumption that everyone must have his chance. It is all the more interesting for an Englishman that Dr Stratton should warn his countrymen that excellence is more important than quantity, that intellectual distinction is more vital than the accumulation of factual knowledge, and that an educated man is distinguished by his attitude towards learning rather than his mastery of a particular domain of knowledge. Stratton has come to fear that Americans will degrade their standards of higher education in order to accommodate all those who aspire to a college degree. He thinks that too many students are entering American universities expecting to be taught rather than being determined to learn.

MIT is responsible for its students throughout their most formative years, when the most important experience they can have is to see new and original work in progress and study with scholars who are actively creating the subjects they teach. The faculty of this great institution is chosen because of the rugged individualism of its members and because of their interest in developing new ideas and creating a new society.

The problems of the president, who has to co-ordinate the efforts of such an undisciplined army and restrain their demands for funds, must have been terribly difficult, but Dr Stratton has studied the welfare of his students as well as encouraging his faculty. He has always believed that his institute should collaborate closely both with local industry and Washington; he sees this policy as the inevitable consequence of the Morrill Act which founded the Land Grant Universities a hundred years ago. They were expected to concern themselves with all the problems of society, whether or not those problems were numbered among the classical academic disciplines.

Engineers have transformed America in the century since MIT was founded. Techniques based on modern science will create the new industries on which the prosperity of America will depend in future. Symbiosis between universities, government and industry is more effective

and more productive in America than it is anywhere else in the world; anyone who has read Stratton's papers will understand why this has come to be so.

The American system is still not appreciated or accepted by many academics in Britain; many of the ideas which led to the Morrill Act and to the foundation of MIT came from England, although we neglected them here for a century after they had shown their promise abroad. It is tragic that we should have to import such things as business schools from America, and it will be futile for us to do so unless we accept the fundamental premise on which everything else depends—American universities have three functions which are equally important. First of all, they must be prepared to study any contemporary problem—they must be centres of innovation. The great American West was conquered in the laboratories of the Land Grant Colleges, and such places as MIT have made a fundamental contribution to the development of the whole of American industry as well as to American business. Secondly, universities must explain their discoveries to anyone of any age who can profit by them; American universities have known for a century that a professional man must be educated and re-educated throughout his working life. Thirdly, of course, universities must teach undergraduates.

Dr Stratton has tried to explain how universities should adapt themselves to these tasks in our changing society, but his main point is that technical progress has become self-sustaining, and the processes of discovery and production feed on each other. The translation of ideas into action is taking place at an ever growing pace, and the line of demarcation between scientist and engineer has almost vanished. It is the great achievement of MIT that it has known this for years, and that it has done more to create this dramatically successful machine than any other institution in the world. Everyone who is interested in our own universities should read Dr Stratton's little book. We shall be learning from it for another twenty years.

VIVIAN BOWDEN

## CHEMISTRY OF SURFACES

## Adsorption, Surface Area and Porosity

By S. J. Gregg and K. S. W. Sing. Pp. xi + 371. (London: Academic Press, Inc. (London), Ltd.; New York: Academic Press, Inc., 1967.) 95s.; \$18.

In their book Gregg and Sing have in general achieved the aim of giving "a critical exposition of the use of adsorption data for the evaluation of the surface area and the pore size distribution of finely divided and porous solids". The book at the same time serves to emphasize the great practical impact the now classic paper of Brunauer, Emmett and Teller has had on studies in surface chemistry; the most theoretical aspects of adsorption have, understandably, not been given comparable prominence. The limitations of the BET equation are discussed, but it should not be forgotten that the essential attribute of this method is its simplicity; any attempt to correct its shortcomings defeats its chief attraction.

It is particularly interesting to note that the physical adsorption of about twenty-five different gases is discussed, while G. D. Halsey expressed the view recently that so long as nitrogen is used as an adsorbate in BET measurements there is no real problem, but when other gases are used the problem is more pressing. Of course, it is not always practical to use nitrogen and this is what the book is particularly concerned with.

There are eight chapters: the first is a useful introduction, the following three deal in turn with non-porous, porous and microporous solids; while the fifth highlights Ross and Olivier's model based on a highly heterogeneous

surface where the distribution of energies is Gaussian. The sixth chapter deals with chemisorption, and I thought this the least critical part of the book. The seventh chapter deals with adsorption from solution, and the last chapter gives some experimental hints for determining isotherms.

The book is relatively free from errors, but I could not overlook some points. Pressures lower than  $10^{-5}$  torr can be measured by a suitably constructed Pirani gauge (page 309), and vacuum conditions are as important in studies of fundamental aspects of physical adsorption as for chemisorption, both phenomena being sensitive to surface topography (compare page 308, where the authors state that a vacuum of  $10^{-5}$  torr is sufficient). The well-defined point *B* reported in reference No. 89 (page 88) was actually at a very low relative pressure (0.01, not 0.1 as stated).

The book is well produced and its content is appropriate for a large number of potential users, which includes undergraduate and postgraduate students and people in industrial research laboratories. There are some 560 references and the figures have a uniform style (Fig. 6.6 excepted!).

M. W. ROBERTS

## LOW TEMPERATURE PHYSICS

### Specific Heats at Low Temperatures

By E. S. R. Gopal. (The International Cryogenics Monograph Series.) Pp. x + 240. (London: Heywood Books, for Iliffe Books, Ltd., 1966.) 70s.; \$11.50.

SOME twenty or so years ago several useful books appeared dealing with physical phenomena of importance at temperatures generally realizable using liquid nitrogen, hydrogen and helium. These books could all be given the same broad title "Low Temperature Physics" and, although the emphasis varied from one publication to another, there was in each an attempt to review a variety of topics from the theoretical and experimental aspects. The wider availability of low temperature facilities and resources since then has greatly speeded the collection of detailed knowledge about the behaviour of matter at low temperatures and this has, of course, stimulated theoretical speculation.

That a series of monographs written by specialists in limited fields is now called for to replace the general books of twenty years ago reflects the general trend of greater specialization which must accomplish greater detailed knowledge. In the circumstances, it is clear that the editors of such a series will exercise their important controlling functions in the choice of individual authors. Let it be said right away that the editors are to be congratulated on their choice of author for this volume. It is no easy task to collect within such a limited compass a sufficient theoretical background with which to compare experimental results and to make the comparisons in a way which retains the active interest of the reader. Dr Gopal has made an excellent selection of topics and dealt with these in an admirable way. The theory is sufficient to make the results intelligible in all cases and although certain readers with particular interests will want to supplement what is given in the book they will find much not requiring any additional reading; the references at the ends of chapters make good starting points for further work.

The arrangement of the book follows a conventional but logical pattern. Starting with some elementary concepts, the author goes on to a discussion of lattice heat capacity, including a very satisfactory introduction to lattice dynamics, and the occurrence of Debye  $\theta$  in other problems of the solid state. The next chapter deals with the electronic heat in metals and alloys, including superconductors, and the relationships to other properties. As

the author states, he cannot do justice to the BCS theory in the space available, but what he does clearly shows the interesting character of the results which can be followed up in the papers referred to at the end of the chapter. The fourth chapter deals with the magnetic contribution to specific heats and I found this a particularly useful chapter. After a brief outline of the thermodynamics of the problem the author deals with specific heat contributions arising from spin waves, ordering processes with reference to the Ising and Heisenberg models and specific heats near the transition temperature, Schottky effects in paramagnetic salts and those arising from nuclear magnetic moments. A useful chapter follows on liquids, most of which is given over to liquid  $^4\text{He}$  and  $^3\text{He}$ , with a brief mention of mixtures of these two liquids.

Although the chapter on the specific heats of gases has to be included for completeness, the material dealt with is readily available in many standard works elsewhere. The final two chapters deal with specific heat anomalies and miscellaneous problems such as specific heats near phase transitions, relaxation of rotational and vibrational specific heats and surface effects.

To some specialists parts of this volume may appear inadequate, but if it had been intended principally for such people it would have taken a different form and certainly not have been condensed into 240 pages. The book can be thoroughly recommended to anyone interested in calorimetry, for Dr Gopal has managed to present a great deal of factual information in a most readable style.

F. E. HOARE

## ENZYMES AND SACCHARIDES

### Methods in Enzymology

Vol. 8. Complex Carbohydrates. Edited by Elizabeth F. Neufeld and Victor Ginsburg. Pp. xxv + 759. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1966.) 208s.

THIS comprehensive volume must be regarded as a complementary volume to *Methods in Carbohydrate Chemistry* by Whistler and Wolfrom. It contains 119 articles written by more than 150 authors from many different laboratories in the world, and it is concerned with methods, including quantitative methods, for dealing with all the enzymes involved in the synthesis and degradation of complex saccharides.

The book starts with a section on analytical methods for estimating simple sugars, particularly those contained in mucopolysaccharides and mucoproteins. Some of the methods, particularly immunological methods and gas chromatography, will be particularly useful at this time.
